ergm.rank-package	*Fit, Simulate and Diagnose Exponential-Family Models for Rank-Order Relational Data*

Description

ergm.rank is a set of extensions to package **ergm** to fit and simulate from exponential-family random graph models for networks whose edge weights are ranks.

Details

Mainly, it implements the `CompleteOrder` reference measure for valued ERGMs (Krivitsky 2012; Krivitsky et al. 2023) and provides some rank-order change statistics (`search.ergmTerms("ordinal")` for a list) (Krivitsky and Butts 2017).

When publishing results obtained using this package, please cite the original authors as described in `citation(package="ergm.rank")`.

All programs derived from this package must cite it.

This package contains functions specific to using `ergm()` to model networks whose dyad values are ranks. Examples include preferences, valued ties reduced to ranks, etc.. These terms have a specialized interpretation, and are therefore generally prefixed by "rank.", though they should take any valued data.

For detailed information on how to download and install the software, go to the Statnet project website: <https://statnet.org>. A tutorial, support newsgroup, references and links to further resources are provided there.

newcomb   *Newcomb's Fraternity Networks*

Description

These 14 networks record weekly sociometric preference rankings from 17 men attending the University of Michigan in the fall of 1956; Data were collected longitudinally over 15 weeks, although data from week 9 are missing.

Format

A list of 15 networks.

Details

The men were recruited to live in off-campus (fraternity) housing, rented for them as part of the Michigan Group Study Project supervised by Theodore Newcomb from 1953 to 1956. All were incoming transfer students with no prior acquaintance of one another.

The data set, derived from one in the unreleased `netdata` package, contains a network list `newcomb` with 14 networks. Each network is complete and contains two edge attributes:

list("rank") the preference of the ith man for the jth man from 1 through 16, with 1 being the highest preference.

list("descrank") the same, but 1 indicates lowest preference.

Examples

```
# Note: This takes a long time.
data(newcomb)

# Fit a model for the transition between initial (time 0) ranking and
# ranking after one week (time 1). Note that MCMC interval has been
# decreased to save time.
newcomb.1.2.fit <- ergm(newcomb[[2]]~
                    rank.inconsistency(newcomb[[1]],"descrank")+
                    rank.deference+rank.nonconformity("all")+
                    rank.nonconformity("localAND"),
                    response="descrank", reference=~CompleteOrder,
                    control=control.ergm(MCMC.interval=10))
```

```
# Check MCMC diagnostics (barely adequate).
mcmc.diagnostics(newcomb.1.2.fit)
summary(newcomb.1.2.fit)
```

---

rank.deference-ergmTerm

Deference (aversion)

Description

Measures the amount of "deference" in the network: configurations where an ego i ranks an alter j over another alter k, but j, in turn, ranks k over i. A lower-than-chance value of this statistic and/or a negative coefficient implies a form of mutuality in the network.

Usage

```
# valued: rank.deference
```

See Also

Keywords: directed, ordinal, triad-related, valued

---

rank.edgecov-ergmTerm   *Dyadic covariates*

Description

Models the effect of a dyadic covariate on the propensity of an ego i to rank alter j highly.

Usage

```
# valued: rank.edgecov(x, attrname)
```

Arguments

x, attrname   a specification for the dyadic covariate: either one of the following, or the name of a network attribute containing one of the following:

a covariate matrix with dimensions $n \times n$ for unipartite networks and $b \times (n - b)$ for bipartite networks; attrname, if given, is used to construct the term name.

a network object with the same size and bipartitedness as LHS; attrname, if given, provides the name of the quantitative edge attribute to use for covariate values (in this case, missing edges in x are assigned a covariate value of zero).

See Also

    Keywords: directed, ordinal, quantitative dyadic attribute, valued

---

rank.inconsistency-ergmTerm

(Weighted) Inconsistency

Description

Measures the amount of disagreement between rankings of the focus network and a fixed covariate network x , by couting the number of pairwise comparisons for which the two networks disagree.

Usage

```
# valued: rank.inconsistency(x, attrname, weights, wtname, wtcenter)
```

Arguments

x, attrname	a specification for the reference ranking: either one of the following, or the name of a network attribute containing one of the following:

    a matrix with dimensions $n \times n$ for unipartite networks and $b \times (n - b)$ for bipartite networks; attrname, if given, is used to construct the term name.

    a network object with the same size and bipartitedness as LHS; attrname, if given, provides the name of the quantitative edge attribute to use for reference rankings values (in this case, missing edges in x are assigned a rank value of zero).

weights	optional parameter to weigh the counts. Can be either a 3D $n \times n \times n$-array whose (i, j, k) th element gives the weight for the comparison by i of j and k or a function taking three arguments, i, j, and k, and returning the weight of this comparison.
wtname, wtcenter	
	If wtcenter=TRUE , the calculated weights will be centered around their mean. wtname can be used to label this term.

---

```
rank.nodeicov-ergmTerm
```
Attractiveness/Popularity covariates

Description

Models the effect of one or more nodal covariates on the propensity of an actor to be ranked highly by the others.

Usage

```
# valued: rank.nodeicov(attr)
```

Arguments

attr   a vertex attribute specification (see Specifying Vertex attributes and Levels (`?nodal_attributes`) for details.)

See Also

[`ergmTerm`](#) for index of model terms currently visible to the package.

   Keywords: directed, ordinal, quantitative nodal attribute, valued

---

```
rank.nonconformity-ergmTerm
```
Nonconformity

Description

Measures the amount of "nonconformity" in the network: configurations where an ego i ranks an alter j over another alter k, but ego l ranks k over j.

Usage

```
# valued: rank.nonconformity(to, par)
```

Arguments

to   which controls to whom an ego may conform:

- `"all"` (the default): Nonconformity to all egos is counted. A lower-than-chance value of this statistic and/or a negative coefficient implies a degree of consensus in the network.

- "localAND": Nonconformity of i to ego l regarding the relative ranking of j and k is only counted if i ranks l over both j and k . A lower-than-chance value of this statistic and/or a negative coefficient implies a form of hierarchical transitivity in the network. This is the recommended form of local nonconformity (over "local1" and "local2").

- "local1": Nonconformity of i to ego l regarding the relative ranking of j and k is only counted if i ranks l over j .

- "local2": Nonconformity of i to ego l regarding the relative ranking of j and k is only counted if i ranks l over k .

- "thresholds": Nonconformity of i to ego l regarding the relative ranking of j and k is only counted if i ranks l above par, where par can be a vector with multiple thresholds.

- "geometric": Nonconformity of i to ego l regarding the relative ranking of j and k is weighted by par taken to the power of the rank of l by i , where par is a scalar.

par   additional parameters for some types of nonconformity.
