Maintainer Savi Virolainen <savi.virolainen@helsinki.fi>

Description Penalized and non-penalized maximum likelihood estimation of smooth
transition vector autoregressive models with various types of transition weight
functions, conditional distributions, and identification methods. Constrained
estimation with various types of constraints is available. Residual based
model diagnostics, forecasting, simulations, counterfactual analysis, and
computation of impulse response functions, generalized impulse response functions,
generalized forecast error variance decompositions, as well as historical
decompositions. See

sstvars-package	*sstvars: toolkit for reduced form and structural smooth transition vector autoregressive models*

Description

sstvars is a package for reduced form and structural smooth transition vector autoregressive models. The package implements various transition weight functions, conditional distributions, identification methods, and parameter restrictions. The model parameters are estimated with the method of maximum likelihood or penalized maximum likelihood by running multiple rounds of either a two-phase estimation procedure or a three-phase procedure. In the former, a genetic algorithm is used to find starting values for a gradient based variable metric algorithm. In the latter, nonlinear least squares (NLS) first used obtain initial estimates for some of the parameters, then a genetic algorithm is used to find starting values for the rest of the parameters conditional on the NLS estimates, and finally a gradient based variable metric algorithm is initialized from the estimates obtained from the previous two steps. For evaluating the adequacy of the estimated models, sstvars utilizes residuals based diagnostics and provides functions for graphical diagnostics as well as for calculating formal diagnostic tests. sstvars also accommodates tools for conducting counterfactual analysis as well as computation of impulse response functions, generalized impulse response functions, generalized forecast error variance decompositions, and historical decompositions. Further functionality includes hypothesis testing, plotting the profile log-likelihood functions about the estimate, simulation from STVAR processes, and forecasting, for example.

The vignette is a good place to start, and see also the readme file.

| acidata | *U.S. Actuaries Climate Index, GDP growth rate, CPI, and interest rate data* |

Description

A monthly U.S. data covering the period from 1961I to 2022III (735 observations) and consisting four variables. First, The Actuaries Climate Index (ACI), which is a measure of the frequency of severe weather and the extend changes in sea levels. Second, the monthly GDP growth rate constructed by the Federal Reserve Bank of Chicago from a collapsed dynamic factor analysis of a panel of 500 monthly measures of real economic activity and quarterly real GDP growth. Third, the monthly growth rate of the consumer price index (CPI). Third, an interest rate variable, which is the effective federal funds rate that is replaced by the the Wu and Xia (2016) shadow rate during zero-lower-bound periods. The Wu and Xia (2016) shadow rate is not bounded by the zero lower bound and also quantifies unconventional monetary policy measures, while it closely follows the federal funds rate when the zero lower bound does not bind.

Usage

```
acidata
```

Format

A numeric matrix of class `'ts'` with 735 rows and 4 columns with one time series in each column:

First column (GDP): The cyclical component of the log of real GDP, https://fred.stlouisfed.org/series/GDPC1.

Second column (GDPDEF): The log-difference of GDP implicit price deflator, https://fred.stlouisfed.org/series/GDPDEF.

Third column (RATE): The Federal funds rate from 1954Q3 to 2008Q2 and after that the Wu and Xia (2016) shadow rate, https://fred.stlouisfed.org/series/FEDFUNDS, https://www.atlantafed.org/cqer/research/wu-xia-shadow-federal-funds-rate.

alt_stvar	*Construct a STVAR model based on results from an arbitrary estimation round of* fitSTVAR

Description

alt_stvar constructs a STVAR model based on results from an arbitrary estimation round of fitSTVAR

Usage

```
alt_stvar(stvar, which_largest = 1, which_round, calc_std_errors = FALSE)
```

Arguments

stvar	object of class "stvar"
which_largest	based on estimation round with which largest log-likelihood should the model be constructed? An integer value in 1,...,nrounds. For example, which_largest=2 would take the second largest log-likelihood and construct the model based on the corresponding estimates.
which_round	based on which estimation round should the model be constructed? An integer value in 1,...,nrounds. If specified, then which_largest is ignored.
calc_std_errors	
	should approximate standard errors be calculated?

Details

It's sometimes useful to examine other estimates than the one with the highest log-likelihood. This function is wrapper around STVAR that picks the correct estimates from an object returned by fitSTVAR.

Value

Returns an S3 object of class 'stvar' defining a smooth transition VAR model. The returned list contains the following components (some of which may be NULL depending on the use case):

data	The input time series data.
model	A list describing the model structure.
params	The parameters of the model.
std_errors	Approximate standard errors of the parameters, if calculated.
transition_weights	
	The transition weights of the model.
regime_cmeans	Conditional means of the regimes, if data is provided.
total_cmeans	Total conditional means of the model, if data is provided.
total_ccovs	Total conditional covariances of the model, if data is provided.

uncond_moments	A list of unconditional moments including regime autocovariances, variances, and means.
residuals_raw	Raw residuals, if data is provided.
residuals_std	Standardized residuals, if data is provided.
structural_shocks	
	Recovered structural shocks, if applicable.
loglik	Log-likelihood of the model, if data is provided.
IC	The values of the information criteria (AIC, HQIC, BIC) for the model, if data is provided.
all_estimates	The parameter estimates from all estimation rounds, if applicable.
all_logliks	The log-likelihood of the estimates from all estimation rounds, if applicable.
which_converged	
	Indicators of which estimation rounds converged, if applicable.
which_round	Indicators of which round of optimization each estimate belongs to, if applicable.
seeds	The seeds used in the estimation in fitSTVAR, if applicable.
LS_estimates	The least squares estimates of the parameters in the form $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$ (intercepts replaced by unconditional means if mean parametrization is used), if applicable.

bound_JSR	*Calculate upper bound for the joint spectral radius of the "companion form AR matrices" of the regimes*

Description

bound_JSR calculates an bounds for the joint spectral radius of the "companion form AR matrices" matrices of the regimes to assess the validity of the stationarity condition.

Usage

```
bound_JSR(
  stvar,
  epsilon = 0.02,
  adaptive_eps = FALSE,
  ncores = 2,
  print_progress = TRUE
)
```

Arguments

stvar   object of class "stvar"

epsilon   a strictly positive real number that approximately defines the goal of length of the interval between the lower and upper bounds. A smaller epsilon value results in a narrower interval, thus providing better accuracy for the bounds, but at

	the cost of increased computational effort. Note that the bounds are always wider than `epsilon` and it is not obvious what `epsilon` should be chosen obtain bounds of specific tightness.
adaptive_eps	logical: if `TRUE`, starts with a large epsilon and then decreases it gradually whenever the progress of the algorithm requires, until the value given in the argument `epsilon` is reached. Usually speeds up the algorithm substantially but is an unconventional approach, and there is no guarantee that the algorithm converges appropriately towards bounds with the tightness given by the argument `epsilon`.
ncores	the number of cores to be used in parallel computing.
print_progress	logical: should the progress of the algorithm be printed?

Details

A sufficient condition for ergodic stationarity of the STVAR processes implemented in `sstvars` is that the joint spectral radius of the "companion form AR matrices" of the regimes is smaller than one (Kheifets and Saikkonen, 2020). This function calculates an upper (and lower) bound for the JSR and is implemented to assess the validity of this condition in practice. If the bound is smaller than one, the model is deemed ergodic stationary.

Implements the branch-and-bound method by Gripenberg (1996) in the conventional form (`adaptive_eps=FALSE`) and in a form incorporating "adaptive tightness" (`adaptive_eps=FALSE`). The latter approach is unconventional and does not guarantee appropriate convergence of the bounds close to the desired tightness given in the argument `epsilon`, but it usually substantially speeds up the algorithm. When `print_progress==TRUE`, the tightest bounds found so-far are printed in each iteration of the algorithm, so you can also just terminate the algorithm when the bounds are tight enough for your purposes. Consider also adjusting the argument `epsilon`, in particular when `adaptive_eps=FALSE`, as larger epsilon does not just make the bounds less tight but also speeds up the algorithm significantly. See Chang and Blondel (2013) for a discussion on variuous methods for bounding the JSR.

Value

Returns lower and upper bounds for the joint spectral radius of the "companion form AR matrices" of the regimes.

## Below examples take approximately 5 seconds to run.

# Gaussian STVAR p=1, M=2 model with weighted relative stationary densities
# of the regimes as the transition weight function:
theta_122relg <- c(0.734054, 0.225598, 0.705744, 0.187897, 0.259626, -0.000863,
  -0.3124, 0.505251, 0.298483, 0.030096, -0.176925, 0.838898, 0.310863, 0.007512,
  0.018244, 0.949533, -0.016941, 0.121403, 0.573269)
mod122 <- STVAR(data=gdpdef, p=1, M=2, params=theta_122relg)

# Absolute values of the eigenvalues of the "companion form AR matrices":
summary(mod122)$abs_boldA_eigens
# It is a necessary (but not sufficient!) condition for ergodic stationary that
# the spectral radius of the "companion form AR matrices" are smaller than one
# for all of the regimes. A sufficient (but not necessary) condition for
# ergodic stationary is that the joint spectral radius of the companion form
# AR matrices" of the regimes is smaller than one. Therefore, we calculate
# bounds for the joint spectral radius.

## Bounds by Gripenberg's (1996) branch-and-bound method:
# Since the largest modulus of the companion form AR matrices is not very close
# to one, we likely won't need very thight bounds to verify the JSR is smaller
# than one. Thus, using a small epsilon would make the algorithm unnecessarily slow,
# so we use the (still quite small) epsilon=0.01:
bound_JSR(mod122, epsilon=0.01, adaptive_eps=FALSE)
# The upper bound is smaller than one, so the model is ergodic stationary.

# If we want tighter bounds, we can set smaller epsilon, e.g., epsilon=0.001:
bound_JSR(mod122, epsilon=0.001, adaptive_eps=FALSE)

# Using adaptive_eps=TRUE usually speeds up the algorithm when the model
# is large, but with the small model here, the speed-difference is small:
bound_JSR(mod122, epsilon=0.001, adaptive_eps=TRUE)
```

---

bound_jsr_G   *Calculate upper bound for the joint spectral radius of a set of matrices*

Description

bound_jsr_G calculates lower and upper bounds for the joint spectral radious of a set of square
matrices, typically the "bold A" matrices, using the algorithm by Gripenberg (1996).

Usage

```
bound_jsr_G(
  S,
  epsilon = 0.01,
  adaptive_eps = FALSE,
```

```
   ncores = 2,
   print_progress = TRUE
)
```

Arguments

S   the set of matrices the bounds should be calculated for in an array, in STVAR
                   applications, all $((dp)x(dp))$ "bold A" (companion form) matrices in a 3D array,
                   so that `[, , m]` gives the matrix the regime `m`.

epsilon   a strictly positive real number that approximately defines the goal of length of
                   the interval between the lower and upper bounds. A smaller epsilon value results
                   in a narrower interval, thus providing better accuracy for the bounds, but at
                   the cost of increased computational effort. Note that the bounds are always
                   wider than `epsilon` and it is not obvious what `epsilon` should be chosen obtain
                   bounds of specific tightness.

adaptive_eps   logical: if `TRUE`, starts with a large epsilon and then decreases it gradually when-
                   ever the progress of the algorithm requires, until the value given in the argument
                   `epsilon` is reached. Usually speeds up the algorithm substantially but is an un-
                   conventional approach, and there is no guarantee that the algorithm converges
                   appropriately towards bounds with the tightness given by the argument `epsilon`.

ncores   the number of cores to be used in parallel computing.

print_progress   logical: should the progress of the algorithm be printed?

Details

The upper and lower bounds are calculated using the Gripenberg's (1996) branch-and-bound method,
which is also discussed in Chang and Blondel (2013). This function can be generally used for ap-
proximating the JSR of a set of square matrices, but the main intention is STVAR applications (for
models created with `sstvars`, the function `bound_JSR` should be preferred). Specifically, Kheifets
and Saikkonen (2020) show that if the joint spectral radius of the companion form AR matrices
of the regimes is smaller than one, the STVAR process is ergodic stationary. Virolainen (2025)
shows the same result for his parametrization of of threshold and smooth transition vector autore-
gressive models. Therefore, if the upper bound is smaller than one, the process is stationary ergodic.
However, as the condition is not necessary but sufficient and also because the bound might be too
conservative, upper bound larger than one does not imply that the process is not ergodic stationary.
You can try higher accuracy, and if the bound is still larger than one, the result does not tell whether
the process is ergodic stationary or not.

Note that with high precision (small `epsilon`), the computational effort required are substantial
and the estimation may take long, even though the function takes use of parallel computing. This is
because with small epsilon the the number of candidate solutions in each iteration may grow expo-
nentially and a large number of iterations may be required. For this reason, `adaptive_eps=TRUE`
can be considered for large matrices, in which case the algorithm starts with a large epsilon, and then
decreases it when new candidate solutions are not found, until the epsilon given by the argument
`epsilon` is reached.

Value

Returns an upper bound for the joint spectral radius of the "companion form AR matrices" of the regimes.

```

---

calc_gradient   *Calculate gradient or Hessian matrix*

Description

`calc_gradient` or `calc_hessian` calculates the gradient or Hessian matrix of the given function at the given point using central difference numerical approximation. `get_gradient` or `get_hessian` calculates the gradient or Hessian matrix of the log-likelihood function at the parameter estimates of a class `'stvar'` object. `get_soc` returns eigenvalues of the Hessian matrix, and `get_foc` is the same as `get_gradient` but named conveniently.

Usage

```
calc_gradient(x, fn, h = 0.001, ...)

calc_hessian(x, fn, h = 0.001, ...)

get_gradient(stvar, ...)

get_hessian(stvar, ...)

get_foc(stvar, ...)

get_soc(stvar, ...)
```

Arguments

x	a numeric vector specifying the point where the gradient or Hessian should be calculated.
fn	a function that takes in argument x as the **first** argument.
h	difference used to approximate the derivatives: either a positive real number of a vector of positive real numbers with the same length as x.
...	other arguments passed to fn (or argument passed to `calc_gradient` or `calc_hessian`).
stvar	object of class `"stvar"`

Details

In particular, the functions `get_foc` and `get_soc` can be used to check whether the found estimates denote a (local) maximum point, a saddle point, or something else. Note that profile log-likelihood functions can be conveniently plotted with the function `profile_logliks`.

Value

Gradient functions return numerical approximation of the gradient and Hessian functions return numerical approximation of the Hessian. `get_soc` returns eigenvalues of the Hessian matrix.

Warning

No argument checks!

Examples

```
# Create a simple function:
foo <- function(x) x^2 + x

# Calculate the gradient at x=1 and x=-0.5:
calc_gradient(x=1, fn=foo)
calc_gradient(x=-0.5, fn=foo)

# Create a more complicated function
foo <- function(x, a, b) a*x[1]^2 - b*x[2]^2

# Calculate the gradient at x=c(1, 2) with parameter values a=0.3 and b=0.1:
calc_gradient(x=c(1, 2), fn=foo, a=0.3, b=0.1)

# Create a linear Gaussian VAR p=1 model:
theta_112 <- c(0.649526, 0.066507, 0.288526, 0.021767, -0.144024, 0.897103,
 0.601786, -0.002945, 0.067224)
mod112 <- STVAR(data=gdpdef, p=1, M=1, params=theta_112)

# Calculate the gradient of the log-likelihood function about the parameter values:
get_foc(mod112)

# Calculate the eigenvalues of the Hessian matrix of the log-likelihood function
# about the parameter values:
get_soc(mod112)
```

---

cfact_fore   *Simulate counterfactual forecast scenarios for structural STVAR models.*

Description

cfact_fore simulates counterfactual forecast scenarios for structural STVAR models.

Usage

```
cfact_fore(
  stvar,
  nsteps,
  nsim = 1000,
  pi = 0.95,
  pred_type = c("mean", "median"),
  exo_weights = NULL,
  cfact_type = c("fixed_path", "muted_response"),
  policy_var = 1,
```

```
  mute_var = NULL,
  cfact_start = 1,
  cfact_end = 1,
  cfact_path = NULL
)

## S3 method for class 'cfactfore'
plot(x, ..., nt, trans_weights = TRUE)

## S3 method for class 'cfactfore'
print(x, ..., digits = 3)
```

Arguments

stvar	an object of class `'stvar'` defining a structural or reduced form STVAR model. For a reduced form model (that is not readily identified statiscally), the shocks are automatically identified by the lower triangular Cholesky decomposition.
nsteps	how many steps ahead should be predicted, i.e., the forecast horizon?
nsim	to how many independent simulations should the forecast be based on?
pi	a numeric vector specifying the confidence levels of the prediction intervals.
pred_type	should the pointforecast be based on sample "median" or "mean"?
exo_weights	if `weight_function="exogenous"`, provide a size $(nsteps x M)$ matrix of exogenous transition weights for the regimes: [step, m] for $step$ steps ahead and regime m weight. Ignored if `weight_function!="exogenous"`.
cfact_type	a character string indicating the type of counterfactual to be computed: should the path of the policy variable be fixed to some hypothetical path (`cfact_type="fixed_path"`) in given forecast horizons or should the responses of the policy variable to lagged and contemporaneous movements of some given variable be muted (`cfact_type="muted_respon`. See details for more information.
policy_var	a positive integer between 1 and d indicating the index of the policy variable considered in the counterfactual scenario.
mute_var	a positive integer between 1 and d indicating the index of the variable to whose lagged movements the policy variable specified in the argument `policy_var` should not react to in the counterfactual scenario. This indicates also the index of the shock to which the policy variable should not react to. It is assumed that `mute_var != policy_var`. This argument is only used when `cfact_type="muted_response"`.
cfact_start	a positive integer between 1 and `nsteps` indicating the starting forecast horizon period for the counterfactual behavior of the specified policy variable.
cfact_end	a positive integer between `cfact_start` and `nsteps` indicating the ending period for the counterfactual behavior of the specified policy variable.
cfact_path	a numeric vector of length `cfact_end-cfact_start+1` indicating the hypothetical path of the policy variable specified in the argument `policy_var`. This argument is only used when `cfact_type="fixed_path"`.
x	object of class `'cfactfore'` created by the function `cfact_fore`.
...	parameters passed to `print.stvarpred` printing the forecast.

nt	a positive integer specifying the number of observations to be plotted along with the forecast.
trans_weights	should forecasts for transition weights be plotted?
digits	how many significant digits to print?

Details

Two types of counterfactual forecast scenarios are accommodated where in given forecast horizons either (1) the policy variable of interest takes some hypothetical path (cfact_type="fixed_path"), or (2) its responses to lagged movements of some given variable and some given shcok are shut off (cfact_type="muted_response"). In both cases, the counterfactual scenarios are simulated by creating hypothetical shocks to the policy variable of interest that yield the counterfactual outcome. This approach has the appealing feature that the counterfactual deviations from the policy reaction function are treated as policy surprises, allowing them to propagate normally, so that the dynamics of the model are not, per se, tampered but just the policy surprises are.

Important: This function assumes that when the policy variable of interest is the i_1th variable, the shock related to it that is manipulated is the i_1th shock. This should be automatically satisfied for recursively identified models, whereas for model identified by heteroskedasticity or non-Gaussianity, the ordering of the shocks can be generally changed without loss of generality with the function reorder_B_columns. In Type (2) counterfactuals it is additionally assumed that, if the variable to whose lagged movements the policy variable should not react to is the i_2th variable, the shock to which the policy variable does not reach to is the i_2th shock.

See the seminal paper of Bernanke et al (1997) for discussing about the "Type (1)" counterfactuals and Kilian and Lewis (2011) for discussion about a type of counterfactual closely related to the "Type (2)" counterfactuals. See Kilian and Lütkepohl (2017), Section 4.4 for further discussion about counterfactual forecast scenarios. The literature cited about considers linear models, but it is explained in the vignette of this package how this function computes the counterfactual forecast scenarios for the STVAR models in a way that accommodates nonlinear time-varying dynamics.

Value

Returns a class 'cfactfore' list with the following elements:

$cfact_pred Counterfactual forecast in a class 'stvarpred' object (see ?predict.stvar).

$pred Forecast that does not impose the counterfactual scenario, in a class 'stvarpred' object.

stvar The original STVAR model object.

input A list containing the arguments used to calculate the counterfactual.

Returns the input object x invisibly.

Functions

- plot(cfactfore): plot method
- print(cfactfore): print method

  cfact_path = NULL
)

## S3 method for class 'cfactgirf'
plot(x, ...)

## S3 method for class 'cfactgirf'
print(x, ..., digits = 3)
```

Arguments

stvar	an object of class 'stvar', created by, e.g., fitSTVAR or fitSSTVAR.
which_shocks	a numeric vector of length at most d (=ncol(data)) and elements in $1, ..., d$ specifying the structural shocks for which the GIRF should be estimated.
shock_size	a non-zero scalar value specifying the common size for all scalar components of the structural shock. Note that the conditional covariance matrix of the structural shock is normalized to an identity matrix and that the (generalized) impulse responses may not be symmetric with respect to the sign and size of the shock.
N	a positive integer specifying the horizon how far ahead should the generalized impulse responses be calculated.

R1	the number of repetitions used to estimate GIRF for each initial value.
R2	the number of initial values to use, i.e., to draw from `init_regime` if `init_values` are not specified. The confidence bounds will be sample quantiles of the GIRFs based on different initial values. Ignored if the argument `init_value` is specified. @param init_regime an integer in $1, ..., M$ specifying the regime from which the initial values should be generated from (see ?simulate.stvar). If `use_data_shocks=TRUE` this is argument not used and `data_girf_pars` should be specified instead.
init_regime	an integer in $1, ..., M$ specifying the regime from which the initial values should be generated from (using a simulation procedure with a burn-in period). For models with Gaussian conditional distribution, it is also possible to generate the starting values from the stationary distribution of a regime. See the details section.
init_values	a size [p, d, R2] array specifying the initial values in each slice for each Monte Carlo repetition, where d is the number of time series in the system and R2 is an argument of this function. In each slice, the **last** row will be used as initial values for the first lag, the second last row for second lag etc. If not specified, initial values will be drawn from the regime specified in `init_regimes`.
which_cumulative	a numeric vector with values in $1, ..., d$ (d=ncol(data)) specifying which the variables for which the impulse responses should be cumulative. Default is none.
scale	should the GIRFs to some of the shocks be scaled so that they correspond to a specific magnitude of instantaneous or peak response of some specific variable (see the argument `scale_type`)? Provide a length three vector where the shock of interest is given in the first element (an integer in $1, ..., d$), the variable of interest is given in the second element (an integer in $1, ..., d$), and the magnitude of its instantaneous or peak response in the third element (a non-zero real number). If the GIRFs of multiple shocks should be scaled, provide a matrix which has one column for each of the shocks with the columns being the length three vectors described above.
scale_type	If argument `scale` is specified, should the GIRFs be scaled to match an instantaneous response ("instant") or peak response ("peak")? If "peak", the scale is based on the largest magnitude of peak response in absolute value. Ignored if `scale` is not specified.
scale_horizon	If `scale_type == "peak"` what the maximum horizon up to which peak response is expected? Scaling won't based on values after this.
ci	a numeric vector with elements in $(0, 1)$ specifying the confidence levels of the "confidence intervals" that **do not** quantify uncertainty about the true parameter value but only uncertainty about the initial value (and possibly sign and size of the shock) within the given regime.
use_data_shocks	set TRUE for a special feature in which for every possible length p history in the data, or a subset of them if so specified in the argument `data_girf_pars`, the GIRF is estimated for a shock that has the sign and size of the corresponding structural shock recovered from the data. If used, the argument `which_shocks` must specify only one shock. See the details section.

data_girf_pars	a length five numeric vector with the following elements determining settings for use_data_shocks=TRUE (concerns the single shock specified in the argument which_shocks):

1. An integer between 0 and M determining the (dominant) regime for which the GIRF should be calculated (0 for all regimes).
2. A number between 0.5 and 1 determining how large transition weight a regime should have to be considered dominant in a given time period (i.e., determining which histories are used to calculate the GIRF if the first element is not 0).
3. Either 0, -1, or 1, determining whether the GIRF should be calculated using shocks of all signs, only negative shocks, or only positive shocks, respectively.
4. Either, 0, 1, or 2, determining whether the GIRF should be calculated using shocks of all sizes, only small shocks, or only large shocks, respectively.
5. A strictly positive real number determining what size shocks are considered large and what size small "in the scale of standard deviations" (for example, if set to 2, shocks larger than that are considered large and shocks smaller than that are considered small; note that the standard deviations of the shocks are normalized to unity).

ncores	the number CPU cores to be used in parallel computing. Only single core computing is supported if an initial value is specified (and the GIRF won't thus be estimated multiple times).
burn_in	Burn-in period for simulating initial values from a regime.
exo_weights	if weight_function="exogenous", provide a size $(N + 1 \times M)$ matrix of exogenous transition weights for the regimes: [h, m] for the (after-the-impact) period $h - 1$ and regime m weight ([1, m] is for the impact period). Ignored if weight_function != "exogenous".
seeds	A numeric vector initializing the seeds for the random number generator for estimation of each GIRF. Should have the length of at least (extra seeds are removed from the end of the vector)...

If initial values are drawn using init_regime**:** R2

If initial values are specified in init_values**:** dim(init_values)[3]

If use_data_shocks=TRUE**:** 1 (the vector of seeds are generated according on the number of histories in the data that satisfy the conditions given in the argument data_girf_pars).

Set NULL for not initializing the seed.

use_parallel	employ parallel computing? If FALSE, does not print anything.
cfact_type	a character string indicating the type of counterfactual to be computed: should the path of the policy variable be fixed to some hypothetical path (cfact_type="fixed_path") in given impulse response horizons or should the responses of the policy variable to lagged and contemporaneous movements of some given variable be muted (cfact_type="muted_response")? See details for more information.
policy_var	a positive integer between 1 and d indicating the index of the policy variable considered in the counterfactual scenario. Note that policy_var is assumed to satisfy !(policy_var %in% which_shocks).

mute_var	a positive integer between 1 and d indicating the index of the variable to whose lagged movements the policy variable specified in the argument `policy_var` should not react to in the counterfactual scenario. This indicates also the index of the shock to which the policy variable should not react to. It is assumed that `mute_var != policy_var`. This argument is only used when `cfact_type="muted_response"`.
cfact_start	a positive integer between 0 and N indicating the starting impulse response horizon period for the counterfactual behavior of the specified policy variable.
cfact_end	a positive integer between `cfact_start` and N indicating the ending period for the counterfactual behavior of the specified policy variable.
cfact_path	a numeric vector of length `cfact_end-cfact_start+1` indicating the hypothetical path of the policy variable specified in the argument `policy_var`. This argument is only used when `cfact_type="fixed_path"`.
x	object of class `'cfactgirf'` created by the function `cfact_girf`.
...	parameters passed to `print.stvargirf` printing the girf.
digits	how many significant digits to print?

Details

Two types of counterfactual generalized impulse response functions (GIRFs) are accommodated where in given impulse response horizons either (1) the policy variable of interest takes some hypothetical path (`cfact_type="fixed_path"`), or (2) its responses to lagged movements of some given variable and some given shock are shut off (`cfact_type="muted_response"`). In both cases, the counterfactual scenarios are simulated by creating hypothetical shocks to the policy variable of interest that yield the counterfactual outcome. This approach has the appealing feature that the counterfactual deviations from the policy reaction function are treated as policy surprises, allowing them to propagate normally, so that the dynamics of the model are not, per se, tampered but just the policy surprises are.

Important: This function assumes that when the policy variable of interest is the i_1th variable, the shock related to it that is manipulated is the i_1th shock. This should be automatically satisfied for recursively identified models, whereas for model identified by heteroskedasticity or non-Gaussianity, the ordering of the shocks can be generally changed without loss of generality with the function `reorder_B_columns`. In Type (2) counterfactuals it is additionally assumed that, if the variable to whose lagged movements the policy variable should not react to is the i_2th variable, the shock to which the policy variable does not reach to is the i_2th shock.

See the seminal paper of Bernanke et al (1997) for discussing about the "Type (1)" counterfactuals and Kilian and Lewis (2011) for discussion about a type of counterfactual closely related to the "Type (2)" counterfactuals. See Kilian and Lütkepohl (2017), Section 4.5 for further discussion about counterfactuals. The literature cited about considers linear models, but it is explained in the vignette of this package how this function computes the historical counterfactuals for the STVAR models in a way that accommodates nonlinear time-varying dynamics.

Value

Returns a class `'cfactgirf'` list with the following elements:

$girf An object of class `'girf'` containing the counterfactual GIRFs (see ?GIRF).

$stvar The original STVAR model object.

$input A list containing the arguments used to calculate the counterfactual.

Returns the input object x invisibly.

Functions

- plot(cfactgirf): plot method
- print(cfactgirf): print method

---

cfact_hist *Simulate historical counterfactual for structural STVAR models.*

Description

cfact_hist simulates historical counterfactual for structural STVAR models.

Usage

```
cfact_hist(
  stvar,
  cfact_type = c("fixed_path", "muted_response"),
  policy_var = 1,
  mute_var = NULL,
  cfact_start = 1,
  cfact_end = 1,
  cfact_path = NULL
)

## S3 method for class 'cfacthist'
plot(x, ...)

## S3 method for class 'cfacthist'
print(x, ..., digits = 3)
```

Arguments

stvar	an object of class `'stvar'` defining a structural or reduced form STVAR model. For a reduced form model (that is not readily identified statiscally), the shocks are automatically identified by the lower triangular Cholesky decomposition.
cfact_type	a character string indicating the type of counterfactual to be computed: should the path of the policy variable be fixed to some hypothetical path (`cfact_type="fixed_path"`) in given points of time or should the responses of the policy variable to lagged and contemporaneous movements of some given variable be muted (`cfact_type="muted_response"`)? See details for more information.
policy_var	a positive integer between 1 and d indicating the index of the policy variable considered in the counterfactual scenario.
mute_var	a positive integer between 1 and d indicating the index of the variable to whose lagged movements the policy variable specified in the argument `policy_var` should not react to in the counterfactual scenario. This indicates also the index of the shock to which the policy variable should not react to. It is assumed that `mute_var != policy_var`. This argument is only used when `cfact_type="muted_response"`.
cfact_start	a positive integer between 1 and T indicating the starting period for the counterfactual behavior of the specified policy variable. It is assumed that the observed time series in indexed as $y_{t-p+1}, ..., y_0, y_1, ..., y_T$, i.e., that the first p observations are the initial values, and the "time period one" observation is the $p+1$th row in the data matrix.

cfact_end	a positive integer between cfact_start and T indicating the ending period for the counterfactual behavior of the specified policy variable.
cfact_path	a numeric vector of length cfact_end-cfact_start+1 indicating the hypothetical path of the policy variable specified in the argument policy_var. This argument is only used when cfact_type="fixed_path".
x	object of class 'cfacthist' created by the function cfact_hist.
...	arguments passed to the function window to select the time periods to print.
digits	how many significant digits to print?

Details

Two types of historical counterfactuals are accommodated where in given historical points of time either (1) the policy variable of interest takes some hypothetical path (cfact_type="fixed_path"), or (2) its responses to lagged movements of some given variable and to some given shock are shut off (cfact_type="muted_response"). In both cases, the counterfactual scenarios are simulated by creating hypothetical shocks to the policy variable of interest that yield the counterfactual outcome. This approach has the appealing feature that the counterfactual deviations from the policy reaction function are treated as policy surprises, allowing them to propagate normally, so that the dynamics of the model are not, per se, tampered but just the policy surprises are.

Important: This function assumes that when the policy variable of interest is the i_1th variable, the shock related to it that is manipulated is the i_1th shock. This should be automatically satisfied for recursively identified models, whereas for model identified by heteroskedasticity or non-Gaussianity, the ordering of the shocks can be generally changed without loss of generality with the function reorder_B_columns. In Type (2) counterfactuals it is additionally assumed that, if the variable to whose lagged movements the policy variable should not react to is the i_2th variable, the shock to which the policy variable does not reach to is the i_2th shock.

See the seminal paper of Bernanke et al (1997) for discussing about the "Type (1)" counterfactuals and Kilian and Lewis (2011) for discussion about the counterfactuals closely related to "Type (2)" counterfactuals. See Kilian and Lütkepohl (2017), Section 4.5 for further discussion about the historical counterfactuals. The literature cited about considers linear models, but it is explained in the vignette of this package how this function computes the historical counterfactuals for the STVAR models in a way that accommodates nonlinear time-varying dynamics.

Value

Returns a class 'cfacthist' list with the following elements:

cfact_data A matrix of size $(T + p \times d)$ containing the counterfactual time series. Note that the first p rows are for the initial values prior the time period $t = 1$.

cfact_shocks A matrix of size $(T \times d)$ containing the counterfactual shocks.

cfact_weights A matrix of size $(T \times M)$ containing the counterfactual transition weights.

stvar The original STVAR model object.

input A list containing the arguments used to calculate the counterfactual.

Returns the input object x invisibly.

Functions

check_params	*Check whether the parameter vector is in the parameter space and throw error if not*

Description

check_params checks whether the parameter vector is in the parameter space.

Usage

```
check_params(
  data,
  p,
  M,
  d,
  params,
 weight_function = c("relative_dens", "logistic", "mlogit", "exponential", "threshold",
    "exogenous"),
  weightfun_pars = NULL,
  cond_dist = c("Gaussian", "Student", "ind_Student", "ind_skewed_t"),
  parametrization = c("intercept", "mean"),
  identification = c("reduced_form", "recursive", "heteroskedasticity",
    "non-Gaussianity"),
  AR_constraints = NULL,
  mean_constraints = NULL,
  weight_constraints = NULL,
  B_constraints = NULL,
  transition_weights,
  allow_unstab = FALSE,
  stab_tol = 0.001,
  posdef_tol = 1e-08,
  distpar_tol = 1e-08,
  weightpar_tol = 1e-08
)
```

Arguments

data	a matrix or class `'ts'` object with d>1 columns. Each column is taken to represent a univariate time series. Missing values are not supported.
p	a positive integer specifying the autoregressive order
M	a positive integer specifying the number of regimes
d	the number of time series in the system, i.e., the dimension
params	a real valued vector specifying the parameter values. Should have the form $\theta = (\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \sigma, \alpha, \nu)$, where (see exceptions below):

- $\phi_m =$ the $(d \times 1)$ intercept (or mean) vector of the mth regime.
- $\varphi_m = (vec(A_{m,1}), ..., vec(A_{m,p}))$ $(pd^2 \times 1)$.
- **if** cond_dist="Gaussian" **or** "Student": $\sigma = (vech(\Omega_1), ..., vech(\Omega_M))$ $(Md(d+1)/2 \times 1)$.
  if cond_dist="ind_Student" **or** "ind_skewed_t": $\sigma = (vec(B_1), ..., vec(B_M))$ $(Md^2 \times 1)$.
- $\alpha =$ the $(a \times 1)$ vector containing the transition weight parameters (see below).

- **if** cond_dist = "Gaussian"): Omit ν from the parameter vector.

  if cond_dist="Student": $\nu > 2$ is the single degrees of freedom parameter.

  if cond_dist="ind_Student": $\nu = (\nu_1, ..., \nu_d)$ $(d \times 1)$, $\nu_i > 2$.

  if cond_dist="ind_skewed_t": $\nu = (\nu_1, ..., \nu_d, \lambda_1, ..., \lambda_d)$ $(2d \times 1)$, $\nu_i > 2$ and $\lambda_i \in (0, 1)$.

For models with...

weight_function="relative_dens": $\alpha = (\alpha_1, ..., \alpha_{M-1})$ $(M-1 \times 1)$, where α_m (1×1), $m = 1, ..., M - 1$ are the transition weight parameters.

weight_function="logistic": $\alpha = (c, \gamma)$ (2×1), where $c \in \mathbb{R}$ is the location parameter and $\gamma > 0$ is the scale parameter.

weight_function="mlogit": $\alpha = (\gamma_1, ..., \gamma_M)$ $((M - 1)k \times 1)$, where γ_m $(k \times 1)$, $m = 1, ..., M - 1$ contains the multinomial logit-regression coefficients of the mth regime. Specifically, for switching variables with indices in $I \subset \{1, ..., d\}$, and with $\tilde{p} \in \{1, ..., p\}$ lags included, γ_m contains the coefficients for the vector $z_{t-1} = (1, \tilde{z}_{\min\{I\}}, ..., \tilde{z}_{\max\{I\}})$, where $\tilde{z}_i = (y_{it-1}, ..., y_{it-\tilde{p}})$, $i \in I$. So $k = 1 + |I|\tilde{p}$ where $|I|$ denotes the number of elements in I.

weight_function="exponential": $\alpha = (c, \gamma)$ (2×1), where $c \in \mathbb{R}$ is the location parameter and $\gamma > 0$ is the scale parameter.

weight_function="threshold": $\alpha = (r_1, ..., r_{M-1})$ $(M - 1 \times 1)$, where $r_1, ..., r_{M-1}$ are the thresholds.

weight_function="exogenous": Omit α from the parameter vector.

AR_constraints: Replace $\varphi_1, ..., \varphi_M$ with ψ as described in the argument AR_constraints.

mean_constraints: Replace $\phi_1, ..., \phi_M$ with $(\mu_1, ..., \mu_g)$ where μ_i, $(d \times 1)$ is the mean parameter for group i and g is the number of groups.

weight_constraints: If linear constraints are imposed, replace α with ξ as described in the argument weigh_constraints. If weight functions parameters are imposed to be fixed values, simply drop α from the parameter vector.

identification="heteroskedasticity": $\sigma = (vec(W), \lambda_2, ..., \lambda_M)$, where W $(d \times d)$ and λ_m $(d \times 1)$, $m = 2, ..., M$, satisfy $\Omega_1 = WW'$ and $\Omega_m = W\Lambda_m W'$, $\Lambda_m = diag(\lambda_{m1}, ..., \lambda_{md})$, $\lambda_{mi} > 0$, $m = 2, ..., M$, $i = 1, ..., d$.

B_constraints: For models identified by heteroskedasticity, replace $vec(W)$ with $\tilde{vec}(W)$ that stacks the columns of the matrix W in to vector so that the elements that are constrained to zero are not included. For models identified by non-Gaussianity, replace $vec(B_1), ..., vec(B_M)$ with similarly with vectorized versions B_m so that the elements that are constrained to zero are not included.

Above, ϕ_m is the intercept parameter, $A_{m,i}$ denotes the ith coefficient matrix of the mth regime, Ω_m denotes the positive definite error term covariance matrix of the mth regime, and B_m is the invertible $(d \times d)$ impact matrix of the mth regime. ν_m is the degrees of freedom parameter of the mth regime. If parametrization=="mean", just replace each ϕ_m with regimewise mean μ_m.

$vec()$ is vectorization operator that stacks columns of a given matrix into a vector. $vech()$ stacks columns of a given matrix from the principal diagonal downwards (including elements on the diagonal) into a vector. $Bvec()$ is a vectorization operator that stacks the columns of a given impact matrix B_m into a vector so that the elements that are constrained to zero by the argument B_constraints are excluded.

weight_function

What type of transition weights $\alpha_{m,t}$ should be used?

"relative_dens": $\alpha_{m,t} = \frac{\alpha_m f_{m,dp}(y_{t-1},...,y_{t-p+1})}{\sum_{n=1}^M \alpha_n f_{n,dp}(y_{t-1},...,y_{t-p+1})}$, where $\alpha_m \in (0,1)$ are weight parameters that satisfy $\sum_{m=1}^M \alpha_m = 1$ and $f_{m,dp}(\cdot)$ is the dp-dimensional stationary density of the mth regime corresponding to p consecutive observations. Available for Gaussian conditional distribution only.

"logistic": $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = [1 + \exp\{-\gamma(y_{it-j} - c)\}]^{-1}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

"mlogit": $\alpha_{m,t} = \frac{\exp\{\gamma_m' z_{t-1}\}}{\sum_{n=1}^M \exp\{\gamma_n' z_{t-1}\}}$, where γ_m are coefficient vectors, $\gamma_M = 0$, and z_{t-1} $(k \times 1)$ is the vector containing a constant and the (lagged) switching variables.

"exponential": $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = 1 - \exp\{-\gamma(y_{it-j} - c)\}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

"threshold": $\alpha_{m,t} = 1$ if $r_{m-1} < y_{it-j} \leq r_m$ and 0 otherwise, where $-\infty \equiv r_0 < r_1 < \cdots < r_{M-1} < r_M \equiv \infty$ are thresholds y_{it-j} is the lag j observation of the ith variable.

"exogenous": Exogenous nonrandom transition weights, specify the weight series in weightfun_pars.

See the vignette for more details about the weight functions.

weightfun_pars **If** weight_function == "relative_dens": Not used.

If weight_function %in% c("logistic", "exponential", "threshold"): a numeric vector with the switching variable $i \in \{1, ..., d\}$ in the first and the lag $j \in \{1, ..., p\}$ in the second element.

If weight_function == "mlogit": a list of two elements:

The first element $vars: a numeric vector containing the variables that should used as switching variables in the weight function in an increasing order, i.e., a vector with unique elements in $\{1, ..., d\}$.

The second element $lags: an integer in $\{1, ..., p\}$ specifying the number of lags to be used in the weight function.

If weight_function == "exogenous": a size (nrow(data) - p x M) matrix containing the exogenous transition weights as [t, m] for time t and regime m. Each row needs to sum to one and only weakly positive values are allowed.

cond_dist specifies the conditional distribution of the model as "Gaussian", "Student", "ind_Student", or "ind_skewed_t", where "ind_Student" the Student's t distribution with independent components, and "ind_skewed_t" is the skewed t distribution with independent components (see Hansen, 1994).

parametrization

> "intercept" or "mean" determining whether the model is parametrized with intercept parameters ϕ_m or regime means μ_m, m=1,...,M.

identification   is it reduced form model or an identified structural model; if the latter, how is it identified (see the vignette or the references for details)?

> "reduced_form": Reduced form model.
>
> "recursive": The usual lower-triangular recursive identification of the shocks via their impact responses.
>
> "heteroskedasticity": Identification by conditional heteroskedasticity, which imposes constant relative impact responses for each shock.
>
> "non-Gaussianity": Identification by non-Gaussianity; requires mutually independent non-Gaussian shocks, thus, currently available only with the conditional distribution "ind_Student".

AR_constraints   a size $(Mpd^2 \times q)$ constraint matrix C specifying linear constraints to the autoregressive parameters. The constraints are of the form $(\varphi_1, ..., \varphi_M) = C\psi$, where $\varphi_m = (vec(A_{m,1}), ..., vec(A_{m,p}))$ $(pd^2 \times 1)$, $m = 1, ..., M$, contains the coefficient matrices and ψ $(q \times 1)$ contains the related parameters. For example, to restrict the AR-parameters to be the identical across the regimes, set $C = [I:...:I]$' $(Mpd^2 \times pd^2)$ where I = diag(p*d^2).

mean_constraints

> Restrict the mean parameters of some regimes to be identical? Provide a list of numeric vectors such that each numeric vector contains the regimes that should share the common mean parameters. For instance, if M=3, the argument list(1, 2:3) restricts the mean parameters of the second and third regime to be identical but the first regime has freely estimated (unconditional) mean. Ignore or set to NULL if mean parameters should not be restricted to be the same among any regimes. This constraint is available only for mean parametrized models; that is, when parametrization="mean".

weight_constraints

> a list of two elements, R in the first element and r in the second element, specifying linear constraints on the transition weight parameters α. The constraints are of the form $\alpha = R\xi + r$, where R is a known $(a \times l)$ constraint matrix of full column rank (a is the dimension of α), r is a known $(a \times 1)$ constant, and ξ is an unknown $(l \times 1)$ parameter. **Alternatively**, set $R = 0$ to constrain the weight parameters to the constant r (in this case, α is dropped from the constrained parameter vector).

B_constraints   a $(d \times d)$ matrix with its entries imposing constraints on the impact matrix B_t: NA indicating that the element is unconstrained, a positive value indicating strict positive sign constraint, a negative value indicating strict negative sign constraint, and zero indicating that the element is constrained to zero. Currently only available for models with identification="heteroskedasticity" or "non-Gaussianity" due to the (in)availability of appropriate parametrizations that allow such constraints to be imposed.

transition_weights

> (optional; only for models with cond_dist="ind_Student" or identification="non-Gaussianity") A $T \times M$ matrix containing the transition weights. If cond_dist="ind_Student" checks that the impact matrix $\sum_{m=1}^{M} \alpha_{m,t}^{1/2} B_m$ is invertible for all $t = 1, ..., T$.

allow_unstab	If TRUE, estimates not satisfying the stability condition are allowed. Always FALSE if weight_function="relative_dens".
stab_tol	numerical tolerance for stability of condition of the regimes: if the "bold A" matrix of any regime has eigenvalues larger that 1 - stat_tol the parameter is considered to be outside the parameter space. Note that if tolerance is too small, numerical evaluation of the log-likelihood might fail and cause error.
posdef_tol	numerical tolerance for positive definiteness of the error term covariance matrices: if the error term covariance matrix of any regime has eigenvalues smaller than this, the parameter is considered to be outside the parameter space. Note that if the tolerance is too small, numerical evaluation of the log-likelihood might fail and cause error.
distpar_tol	the parameter vector is considered to be outside the parameter space if the degrees of freedom parameters is not larger than 2 + distpar_tol (applies only if cond_dist="Student").
weightpar_tol	numerical tolerance for weight parameters being in the parameter space. Values closer to to the border of the parameter space than this are considered to be "outside" the parameter space.

Value

Throws an informative error if there is something wrong with the parameter vector.

diagnostic_plot   *Residual diagnostic plot for a STVAR model*

Description

`diagnostic_plot` plots a multivariate residual diagnostic plot for either autocorrelation, conditional heteroskedasticity, or distribution, or simply draws the residual time series.

Usage

```
diagnostic_plot(
  stvar,
  type = c("all", "series", "ac", "ch", "dist"),
  resid_type = c("standardized", "raw"),
  maxlag = 12
)
```

Arguments

stvar   object of class `"stvar"`

type   which type of diagnostic plot should be plotted?

- `"all"` all below sequentially.
- `"series"` the residual time series.
- `"ac"` the residual autocorrelation and cross-correlation functions.
- `"ch"` the squared residual autocorrelation and cross-correlation functions.
- `"dist"` the residual histogram with theoretical density (dashed line) and QQ-plots.

resid_type   should standardized or raw residuals be used?

maxlag   the maximum lag considered in types `"ac"` and `"ch"`.

Details

Auto- and cross-correlations (types `"ac"` and `"ch"`) are calculated with the function `acf` from the package `stats` and the plot method for class `'acf'` objects is employed.

If `cond_dist == "Student"` or `"ind_Student"`, the estimates of the degrees of freedom parameters is used in theoretical densities and quantiles. If `cond_dist == "ind_skewed_t"`, the estimates of the degrees of freedom and skewness parameters are used in theoretical densities and quantiles, and the quantile function is computed numerically.

Value

No return value, called for its side effect of plotting the diagnostic plot.

diag_Omegas   *Simultaneously diagonalize two covariance matrices*

Description

`diag_Omegas` Simultaneously diagonalizes two covariance matrices using eigenvalue decomposition.

Usage

```
diag_Omegas(Omega1, Omega2)
```

Arguments

Omega1   a positive definite (dxd) covariance matrix $(d > 1)$

Omega2   another positive definite (dxd) covariance matrix

Details

See the return value and Muirhead (1982), Theorem A9.9 for details.

Value

Returns a length $d^2 + d$ vector where the first d^2 elements are $vec(W)$ with the columns of W being (specific) eigenvectors of the matrix $\Omega_2\Omega_1^{-1}$ and the rest d elements are the corresponding eigenvalues "lambdas". The result satisfies $WW' = Omega1$ and $W diag(lambdas)W' = Omega2$.

If `Omega2` is not supplied, returns a vectorized symmetric (and pos. def.) square root matrix of `Omega1`.

Warning

No argument checks! Does not work with dimension $d = 1$!

References

- Muirhead R.J. 1982. Aspects of Multivariate Statistical Theory, *Wiley*.

Examples

```
# Create two (2x2) coviance matrices using the parameters W and lambdas:
d <- 2 # The dimension
W0 <- matrix(1:(d^2), nrow=2) # W
lambdas0 <- 1:d # The eigenvalues
(Omg1 <- W0%*%t(W0)) # The first covariance matrix
(Omg2 <- W0%*%diag(lambdas0)%*%t(W0)) # The second covariance matrix

# Then simultaneously diagonalize the covariance matrices:
res <- diag_Omegas(Omg1, Omg2)

# Recover W:
W <- matrix(res[1:(d^2)], nrow=d, byrow=FALSE)
tcrossprod(W) # == Omg1, the first covariance matrix

# Recover lambdas:
lambdas <- res[(d^2 + 1):(d^2 + d)]
W%*%diag(lambdas)%*%t(W) # == Omg2, the second covariance matrix
```

---

filter_estimates	*Filter inappropriate the estimates produced by fitSTVAR*

Description

`filter_estimates` filters out inappropriate estimates produced by `fitSTVAR`: can be used to obtain the (possibly) appropriate estimate with the largest found log-likelihood (among possibly appropriate estimates) as well as (possibly) appropriate estimates based on smaller log-likelihoods.

Usage

```
filter_estimates(
  stvar,
  which_largest = 1,
  filter_stab = TRUE,
  calc_std_errors = FALSE
)
```

Arguments

stvar	a class 'stvar' object defining a structural STVAR model that is identified by heteroskedasticity or non-Gaussianity, typically created with `fitSSTVAR`.
which_largest	an integer at least one specifying the (possibly) appropriate estimate corresponding to which largest log-likelihood should be returned. E.g., if `which_largest=2`, the function will return among the estimates that it does not deem inappropriate the one that has the second largest log-likelihood.

filter_stab	Should estimates close to breaking the usual stability condition be filtered out?
calc_std_errors	
	should approximate standard errors be calculated?

Details

The function goes through the estimates produced by `fitSTVAR` and checks which estimates are deemed inappropriate. That is, estimates that are not likely solutions of interest. Specifically, solutions that incorporate a near-singular error term covariance matrix (any eigenvalue less than 0.002), any modulus of the eigenvalues of the companion form AR matrices larger than 0.9985 (indicating the necessary condition for stationarity is close to break), or transition weights such that they are close to zero for almost all t for at least one regime. Then, among the solutions are not deemed inappropriate, it returns a STVAR models based on the estimate that has the `which_largest` largest log-likelihood.

The function `filter_estimates` is kind of a version of `alt_stvar` that only considers estimates that are not deemed inappropriate

Value

Returns an S3 object of class `'stvar'` defining a smooth transition VAR model. The returned list contains the following components (some of which may be `NULL` depending on the use case):

data	The input time series data.
model	A list describing the model structure.
params	The parameters of the model.
std_errors	Approximate standard errors of the parameters, if calculated.
transition_weights	
	The transition weights of the model.
regime_cmeans	Conditional means of the regimes, if data is provided.
total_cmeans	Total conditional means of the model, if data is provided.
total_ccovs	Total conditional covariances of the model, if data is provided.
uncond_moments	A list of unconditional moments including regime autocovariances, variances, and means.
residuals_raw	Raw residuals, if data is provided.
residuals_std	Standardized residuals, if data is provided.
structural_shocks	
	Recovered structural shocks, if applicable.
loglik	Log-likelihood of the model, if data is provided.
IC	The values of the information criteria (AIC, HQIC, BIC) for the model, if data is provided.
all_estimates	The parameter estimates from all estimation rounds, if applicable.
all_logliks	The log-likelihood of the estimates from all estimation rounds, if applicable.
which_converged	
	Indicators of which estimation rounds converged, if applicable.

which_round	Indicators of which round of optimization each estimate belongs to, if applicable.
seeds	The seeds used in the estimation in fitSTVAR, if applicable.
LS_estimates	The least squares estimates of the parameters in the form $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$ (intercepts replaced by unconditional means if mean parametrization is used), if applicable.

fitSSTVAR	*Maximum likelihood estimation of a structural STVAR model based on preliminary estimates from a reduced form model.*

Description

fitSSTVAR uses a robust method and a variable metric algorithm to estimate a structural STVAR model based on preliminary estimates from a reduced form model.

Usage

```
fitSSTVAR(
  stvar,
  identification = c("recursive", "heteroskedasticity", "non-Gaussianity"),
  B_constraints = NULL,
  B_pm_reg = NULL,
  B_perm = NULL,
  B_signs = NULL,
  maxit = 1000,
  maxit_robust = 1000,
  h = 0.001,
  robust_method = c("Nelder-Mead", "SANN", "none"),
  print_res = TRUE,
  calc_std_errors = TRUE
)
```

Arguments

stvar	a an object of class 'stvar', created by, e.g., fitSTVAR, specifying a reduced form or a structural model
identification	Which identification should the structural model use? (see the vignette or the references for details)

"recursive": The usual lower-triangular recursive identification of the shocks via their impact responses.

"heteroskedasticity": Identification by conditional heteroskedasticity, which imposes constant relative impact responses for each shock.

B_constraints	Employ further constraints on the impact matrix? A $(d \times d)$ matrix with its entries imposing constraints on the impact matrix B_t: NA indicating that the element is unconstrained, a positive value indicating strict positive sign constraint, a negative value indicating strict negative sign constraint, and zero indicating that the element is constrained to zero. Currently only available for models with identification="heteroskedasticity" due to the (in)availability of appropriate parametrizations that allow such constraints to be imposed.
B_pm_reg	an integer between 1 and M specifying the regime the permutations and sign changes of B_m specified in the arguments B_perm and B_signs are applied to.
B_perm	a numeric vector of length d specifying the permutation of the columns of the impact matrix B_m of a single regime specified in the argument B_pm_reg prior to re-estimating the model. Applicable only for models with cond_dist = "ind_Student" or "ind_skewed_t".
B_signs	a numeric vector specifying the columns of the impact matrix of a single regime specified in the argument B_pm_reg that should be multiplied by -1 **prior** to reordering them according to B_perm (if specified). Applicable only for models with cond_dist = "ind_Student" or "ind_skewed_t".
maxit	the maximum number of iterations in the variable metric algorithm.
maxit_robust	the maximum number of iterations on the first phase robust estimation, if employed.
h	the strictly positive difference used in the finite difference approximation of the gradient used in numerical optimization.
robust_method	Should some robust estimation method be used in the estimation before switching to the gradient based variable metric algorithm? See details.
print_res	should summaries of estimation results be printed?
calc_std_errors	
	Calculate approximate standard errors (based on standard asymptotics)?

Details

When the structural model does not impose overidentifying constraints, it is directly obtained from the reduced form model, and estimation is not required. When overidentifying constraints are imposed, the model is estimated subject to the constraints.

Using the robust estimation method before switching to the variable metric can be useful if the initial estimates are not very close to the ML estimate of the structural model, as the variable metric

algorithm (usually) converges to a nearby local maximum or saddle point. However, if the initial estimates are far from the ML estimate, the resulting solution is likely local only due to the complexity of the model. Note that Nelder-Mead algorithm is much faster than SANN but can get stuck at a local solution. This is particularly the case when the imposed overidentifying restrictions are such that the unrestricted estimate is not close to satisfying them. Nevertheless, in most practical cases, the model is just identified and estimation is not required, and often reasonable overidentifying constraints are close to the unrestricted estimate.

Employs the estimation function `optim` from the package `stats` that implements the optimization algorithms. See ?optim for the documentation on the optimization methods.

The arguments `B_pm_reg`, `B_perm`, and `B_signs` can be used to explore estimates based various orderings and sign changes of the columns of the impact matrices B_m of specific regimes. This can be useful in the presence of weak identification with respect to the ordering or signs of the columns $B_2, ..., B_M$ (see Virolainen 2025).

Value

Returns an S3 object of class `'stvar'` defining a smooth transition VAR model. The returned list contains the following components (some of which may be `NULL` depending on the use case):

`data`	The input time series data.
`model`	A list describing the model structure.
`params`	The parameters of the model.
`std_errors`	Approximate standard errors of the parameters, if calculated.
`transition_weights`	
	The transition weights of the model.
`regime_cmeans`	Conditional means of the regimes, if data is provided.
`total_cmeans`	Total conditional means of the model, if data is provided.
`total_ccovs`	Total conditional covariances of the model, if data is provided.
`uncond_moments`	A list of unconditional moments including regime autocovariances, variances, and means.
`residuals_raw`	Raw residuals, if data is provided.
`residuals_std`	Standardized residuals, if data is provided.
`structural_shocks`	
	Recovered structural shocks, if applicable.
`loglik`	Log-likelihood of the model, if data is provided.
`IC`	The values of the information criteria (AIC, HQIC, BIC) for the model, if data is provided.
`all_estimates`	The parameter estimates from all estimation rounds, if applicable.
`all_logliks`	The log-likelihood of the estimates from all estimation rounds, if applicable.
`which_converged`	
	Indicators of which estimation rounds converged, if applicable.
`which_round`	Indicators of which round of optimization each estimate belongs to, if applicable.

seeds   The seeds used in the estimation in `fitSTVAR`, if applicable.

LS_estimates   The least squares estimates of the parameters in the form $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$
                   (intercepts replaced by unconditional means if mean parametrization is used), if
                   applicable.

```

fitSTVAR	*Two-phase or three-phase (penalized) maximum likelihood estimation of a reduced form smooth transition VAR model*

Description

`fitSTVAR` estimates a reduced form smooth transition VAR model in two phases or three phases. In additional ML estimation, also penalized ML estimation is available.

Usage

```
fitSTVAR(
  data,
  p,
  M,
 weight_function = c("relative_dens", "logistic", "mlogit", "exponential", "threshold",
    "exogenous"),
  weightfun_pars = NULL,
  cond_dist = c("Gaussian", "Student", "ind_Student", "ind_skewed_t"),
  parametrization = c("intercept", "mean"),
  AR_constraints = NULL,
  mean_constraints = NULL,
  weight_constraints = NULL,
  estim_method,
  penalized,
  penalty_params = c(0.05, 0.2),
  allow_unstab,
  min_obs_coef = 3,
  sparse_grid = FALSE,
```

```
    h = 0.001,
    nrounds,
    ncores = 2,
    maxit = 2000,
    seeds = NULL,
    print_res = TRUE,
    use_parallel = TRUE,
    calc_std_errors = TRUE,
    ...
)
```

Arguments

data
: a matrix or class `'ts'` object with d>1 columns. Each column is taken to represent a univariate time series. Missing values are not supported.

p
: a positive integer specifying the autoregressive order

M
: a positive integer specifying the number of regimes

weight_function
:
What type of transition weights $\alpha_{m,t}$ should be used?

"relative_dens": $\alpha_{m,t} = \frac{\alpha_m f_{m,dp}(y_{t-1},...,y_{t-p+1})}{\sum_{n=1}^{M} \alpha_n f_{n,dp}(y_{t-1},...,y_{t-p+1})}$, where $\alpha_m \in (0,1)$ are weight parameters that satisfy $\sum_{m=1}^{M} \alpha_m = 1$ and $f_{m,dp}(\cdot)$ is the dp-dimensional stationary density of the mth regime corresponding to p consecutive observations. Available for Gaussian conditional distribution only.

"logistic": $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = [1 + \exp\{-\gamma(y_{it-j} - c)\}]^{-1}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

"mlogit": $\alpha_{m,t} = \frac{\exp\{\gamma_m' z_{t-1}\}}{\sum_{n=1}^{M} \exp\{\gamma_n' z_{t-1}\}}$, where γ_m are coefficient vectors, $\gamma_M = 0$, and z_{t-1} ($k \times 1$) is the vector containing a constant and the (lagged) switching variables.

"exponential": $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = 1 - \exp\{-\gamma(y_{it-j} - c)\}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

"threshold": $\alpha_{m,t} = 1$ if $r_{m-1} < y_{it-j} \leq r_m$ and 0 otherwise, where $-\infty \equiv r_0 < r_1 < \cdots < r_{M-1} < r_M \equiv \infty$ are thresholds y_{it-j} is the lag j observation of the ith variable.

"exogenous": Exogenous nonrandom transition weights, specify the weight series in `weightfun_pars`.

See the vignette for more details about the weight functions.

weightfun_pars
: **If** `weight_function == "relative_dens"`: Not used.

If `weight_function %in% c("logistic", "exponential", "threshold")`: a numeric vector with the switching variable $i \in \{1, ..., d\}$ in the first and the lag $j \in \{1, ..., p\}$ in the second element.

If `weight_function == "mlogit"`: a list of two elements:

The first element `$vars`: a numeric vector containing the variables that should used as switching variables in the weight function in an increasing order, i.e., a vector with unique elements in $\{1, ..., d\}$.

           The second element `$lags`: an integer in $\{1, ..., p\}$ specifying the number of lags to be used in the weight function.

           If `weight_function == "exogenous"`: a size (`nrow(data) - p x M`) matrix containing the exogenous transition weights as `[t, m]` for time t and regime m. Each row needs to sum to one and only weakly positive values are allowed.

cond_dist   specifies the conditional distribution of the model as `"Gaussian"`, `"Student"`, `"ind_Student"`, or `"ind_skewed_t"`, where `"ind_Student"` the Student's t distribution with independent components, and `"ind_skewed_t"` is the skewed t distribution with independent components (see Hansen, 1994).

parametrization

        `"intercept"` or `"mean"` determining whether the model is parametrized with intercept parameters ϕ_m or regime means μ_m, m=1,...,M.

AR_constraints   a size $(Mpd^2 \times q)$ constraint matrix C specifying linear constraints to the autoregressive parameters. The constraints are of the form $(\varphi_1, ..., \varphi_M) = C\psi$, where $\varphi_m = (vec(A_{m,1}), ..., vec(A_{m,p}))$ $(pd^2 \times 1)$, $m = 1, ..., M$, contains the coefficient matrices and ψ $(q \times 1)$ contains the related parameters. For example, to restrict the AR-parameters to be the identical across the regimes, set $C = [\text{I}: ...: \text{I}]'$ $(Mpd^2 \times pd^2)$ where `I = diag(p*d^2)`.

mean_constraints

        Restrict the mean parameters of some regimes to be identical? Provide a list of numeric vectors such that each numeric vector contains the regimes that should share the common mean parameters. For instance, if M=3, the argument `list(1, 2:3)` restricts the mean parameters of the second and third regime to be identical but the first regime has freely estimated (unconditional) mean. Ignore or set to `NULL` if mean parameters should not be restricted to be the same among any regimes. This constraint is available only for mean parametrized models; that is, when `parametrization="mean"`.

weight_constraints

        a list of two elements, R in the first element and r in the second element, specifying linear constraints on the transition weight parameters α. The constraints are of the form $\alpha = R\xi + r$, where R is a known $(a \times l)$ constraint matrix of full column rank (a is the dimension of α), r is a known $(a \times 1)$ constant, and ξ is an unknown $(l \times 1)$ parameter. **Alternatively**, set $R = 0$ to constrain the weight parameters to the constant r (in this case, α is dropped from the constrained parameter vector).

estim_method   either `"two-phase"` or `"three-phase"` (the former is the default method for `relative_dens` models and the latter the default for the other models). See details.

penalized   should penalized log-likelihood function be used that penalizes the log-likelihood function when the parameter values are close the boundary of the stability region or outside it? If TRUE, estimates that do not satisfy the stability condition are allowed (except when `weight_function="relative_dens"`). The default is TRUE for three-phase estimation and FALSE for two-phase estimation.

penalty_params   a numeric vector with two positive elements specifying the penalization parameters: the first element determined how far from the boundary of the stability region the penalization starts (a number between zero and one, smaller number

	starts penalization closer to the boundary) and the second element is a tuning parameter for the penalization (a positive real number, a higher value penalizes non-stability more).
allow_unstab	If TRUE, estimates not satisfying the stability condition are allowed. Always FALSE if weight_function="relative_dens".
min_obs_coef	In the LS/NLS step of the three phase estimation, the smallest accepted number of observations (times variables) from each regime relative to the number of parameters in the regime. For models with AR constraints, the number of AR matrix parameters in each regimes is simply assumed to be ncol(AR_constraints)/M.
sparse_grid	should the grid of weight function values in LS/NLS estimation be more sparse (speeding up the estimation)?
h	the strictly positive difference used in the finite difference approximation of the gradient used in numerical optimization.
nrounds	the number of estimation rounds that should be performed. The default is (M*ncol(data))^3 when estim_method="two-phase" and (M*ncol(data))^2 when estim_method="three-phase".
ncores	the number CPU cores to be used in parallel computing.
maxit	the maximum number of iterations in the variable metric algorithm.
seeds	a length nrounds vector containing the random number generator seed for each call to the genetic algorithm, or NULL for not initializing the seed.
print_res	should summaries of estimation results be printed?
use_parallel	employ parallel computing? If use_parallel=FALSE && print_res=FALSE, nothing is printed during the estimation process.
calc_std_errors	
	Calculate approximate standard errors (based on standard asymptotics)?
...	additional settings passed to the function GAfit employing the genetic algorithm.

Details

If you wish to estimate a structural model, estimate first the reduced form model and then use the use the function fitSSTVAR to create (and estimate if necessary) the structural model based on the estimated reduced form model.

three-phase estimation. With estim_method="three-phase" (not available for models with relative_dens weight function), an extra phase is added to the beginning of the two-phase estimation procedure: the autoregressive and weight function parameters are first estimated by the method of (penalized) least squares. Then, the rest of the parameters are estimated by (penalized) ML with the genetic algorithm conditionally on the LS estimates. Finally, all the parameters are estimated by (penalized) ML by initializing a gradient based variable metric algorithm from initial estimates obtained from the first two phases. This allows to use substantially decrease the required number of estimation rounds, and thereby typically speeds up the estimation substantially. On the other hand, the three-phase procedure tends to produce estimates close to the initial (penalized) LS estimates, while the two-phase procedure explores the parameter space more thoroughly (when a large enough number of estimation rounds is ran).

Penalized estimation. The penalized estimation (penalized=TRUE) maximizes the penalized log-likelihood function in which a penalty term is added. The penalty term becomes nonzero when

the parameter values are close to the boundary of the stability region or outside it, it increases in the modulus of the eigenvalues of the companion form AR matrices of the regimes. With `allow_unstab=TRUE`, allowing for unstable estimates, it allows the estimation algorithms to explore the parameter space outside the stability region, but with high enough penalization, the optimization algorithm eventually converges back to the stability region. By default, penalized estimation (with unstable estimates allow) is used for `estim_method="three-phase"` and not used for `estim_method="two-phase"`.

The rest concerns both two-phase and three-phase procedures.** Because of complexity and high multimodality of the log-likelihood function, it is **not certain that the estimation algorithm will end up in the global maximum point. When `estim_method="two-phase"`, it is expected that many of the estimation rounds will end up in some local maximum or a saddle point instead. Therefore, a (sometimes very large) number of estimation rounds is required for reliable results (when `estim_method="three-phase"` substantially smaller number should be sufficient). Due to identification problems and high complexity of the surface of the log-likelihood function, the estimation may fail especially in the cases where the number of regimes is chosen too large.

The estimation process is computationally heavy and it might take considerably long time for large models to estimate, particularly if `estim_method="two-phase"`. Note that reliable estimation of model with `cond_dist == "ind_Student"` or `"ind_skewed_t"` is more difficult than with Gaussian or Student's t models due to the increased complexity.

If the iteration limit `maxit` in the variable metric algorithm is reached, one can continue the estimation by iterating more with the function `iterate_more`. Alternatively, one may use the found estimates as starting values for the genetic algorithm and employ another round of estimation (see `??GAfit` how to set up an initial population with the dot parameters).

If the estimation algorithm performs poorly, it usually helps to scale the individual series so that they vary roughly in the same scale. This makes it is easier to draw reasonable AR coefficients and (with some weight functions) weight parameter values in the genetic algorithm. Even if the estimation algorithm somewhat works, it should be preferred to scale the data so that most of the AR coefficients will not be very large, as the genetic algorithm works better with relatively small AR coefficients. If needed, another package can be used to fit linear VARs to the series to see which scaling of the series results in relatively small AR coefficients. You should avoid very small (or very high) variance in the data as well, so that the eigenvalues of the covariance matrices are in a reasonable range.

weight_constraints: If you are using weight constraints other than restricting some of the weight parameters to known constants, make sure the constraints are sensible. Otherwise, the estimation may fail due to the estimation algorithm not being able to generate reasonable random guesses for the values of the constrained weight parameters.

Filtering inappropriate estimates: `fitSTVAR` automatically filters through estimates that it deems "inappropriate". That is, estimates that are not likely solutions of interest. Specifically, solutions that incorporate a near-singular error term covariance matrix (any eigenvalue less than 0.002), any modulus of the eigenvalues of the companion form AR matrices larger than 0.9985 (indicating the necessary condition for stationarity is close to break), or transition weights such that they are close to zero for almost all t for at least one regime. You can also always find the solutions of interest yourself by using the function `alt_stvar` as well since results from all estimation rounds are saved).

Passing arguments to the genetic algorithm: The settings of the genetic algorithm can be adjusted by passing arguments to it via the dot parameters. See all the available options from the documentation of the function `GAfit` with the command `??GAfit`.

Value

Returns an S3 object of class `'stvar'` defining a smooth transition VAR model. The returned list contains the following components (some of which may be `NULL` depending on the use case):

`data`	The input time series data.
`model`	A list describing the model structure.
`params`	The parameters of the model.
`std_errors`	Approximate standard errors of the parameters, if calculated.
`transition_weights`	
	The transition weights of the model.
`regime_cmeans`	Conditional means of the regimes, if data is provided.
`total_cmeans`	Total conditional means of the model, if data is provided.
`total_ccovs`	Total conditional covariances of the model, if data is provided.
`uncond_moments`	A list of unconditional moments including regime autocovariances, variances, and means.
`residuals_raw`	Raw residuals, if data is provided.
`residuals_std`	Standardized residuals, if data is provided.
`structural_shocks`	
	Recovered structural shocks, if applicable.
`loglik`	Log-likelihood of the model, if data is provided.
`IC`	The values of the information criteria (AIC, HQIC, BIC) for the model, if data is provided.
`all_estimates`	The parameter estimates from all estimation rounds, if applicable.
`all_logliks`	The log-likelihood of the estimates from all estimation rounds, if applicable.
`which_converged`	
	Indicators of which estimation rounds converged, if applicable.
`which_round`	Indicators of which round of optimization each estimate belongs to, if applicable.
`seeds`	The seeds used in the estimation in `fitSTVAR`, if applicable.
`LS_estimates`	The least squares estimates of the parameters in the form $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$ (intercepts replaced by unconditional means if mean parametrization is used), if applicable.

S3 methods

The following S3 methods are supported for class `'stvar'`: `logLik`, `residuals`, `print`, `summary`, `predict`, `simulate`, and `plot`.

GAfit   *Genetic algorithm for preliminary estimation of reduced form STVAR*
                               models

Description

`GAfit` estimates the specified reduced form STVAR model using a genetic algorithm. It is designed to find starting values for gradient based methods and NOT to obtain final estimates constituting a local maximum.

Usage

```
GAfit(
  data,
  p,
  M,
 weight_function = c("relative_dens", "logistic", "mlogit", "exponential", "threshold",
    "exogenous"),
  weightfun_pars = NULL,
  cond_dist = c("Gaussian", "Student", "ind_Student", "ind_skewed_t"),
  parametrization = c("intercept", "mean"),
  AR_constraints = NULL,
  mean_constraints = NULL,
  weight_constraints = NULL,
  ngen = 200,
  popsize,
  smart_mu = min(100, ceiling(0.5 * ngen)),
  initpop = NULL,
  mu_scale,
  mu_scale2,
  omega_scale,
  B_scale,
  weight_scale,
  ar_scale = 0.2,
  upper_ar_scale = 1,
  ar_scale2 = 1,
  regime_force_scale = 1,
  penalized,
  penalty_params = c(0.05, 0.5),
  allow_unstab,
  red_criteria = c(0.05, 0.01),
  bound_by_weights = FALSE,
  min_obs_coef_ga = 2.5,
```

```
    pre_smart_mu_prob = 0,
    to_return = c("alt_ind", "best_ind"),
    minval,
    fixed_params = NULL,
    fixed_params_in_smart_mu = TRUE,
    seed = NULL
)
```

Arguments

data	a matrix or class `'ts'` object with d>1 columns. Each column is taken to represent a univariate time series. Missing values are not supported.
p	a positive integer specifying the autoregressive order
M	a positive integer specifying the number of regimes
weight_function	

What type of transition weights $\alpha_{m,t}$ should be used?

"relative_dens": $\alpha_{m,t} = \frac{\alpha_m f_{m,dp}(y_{t-1},...,y_{t-p+1})}{\sum_{n=1}^{M} \alpha_n f_{n,dp}(y_{t-1},...,y_{t-p+1})}$, where $\alpha_m \in (0,1)$ are weight parameters that satisfy $\sum_{m=1}^{M} \alpha_m = 1$ and $f_{m,dp}(\cdot)$ is the dp-dimensional stationary density of the mth regime corresponding to p consecutive observations. Available for Gaussian conditional distribution only.

"logistic": $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = [1 + \exp\{-\gamma(y_{it-j} - c)\}]^{-1}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

"mlogit": $\alpha_{m,t} = \frac{\exp\{\gamma'_m z_{t-1}\}}{\sum_{n=1}^{M} \exp\{\gamma'_n z_{t-1}\}}$, where γ_m are coefficient vectors, $\gamma_M = 0$, and z_{t-1} $(k \times 1)$ is the vector containing a constant and the (lagged) switching variables.

"exponential": $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = 1 - \exp\{-\gamma(y_{it-j} - c)\}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

"threshold": $\alpha_{m,t} = 1$ if $r_{m-1} < y_{it-j} \leq r_m$ and 0 otherwise, where $-\infty \equiv r_0 < r_1 < \cdots < r_{M-1} < r_M \equiv \infty$ are thresholds y_{it-j} is the lag j observation of the ith variable.

"exogenous": Exogenous nonrandom transition weights, specify the weight series in `weightfun_pars`.

See the vignette for more details about the weight functions.

weightfun_pars	**If** `weight_function == "relative_dens"`: Not used.

If `weight_function %in% c("logistic", "exponential", "threshold")`: a numeric vector with the switching variable $i \in \{1, ..., d\}$ in the first and the lag $j \in \{1, ..., p\}$ in the second element.

If `weight_function == "mlogit"`: a list of two elements:

The first element `$vars`: a numeric vector containing the variables that should used as switching variables in the weight function in an increasing order, i.e., a vector with unique elements in $\{1, ..., d\}$.

The second element `$lags`: an integer in $\{1, ..., p\}$ specifying the number of lags to be used in the weight function.

If `weight_function == "exogenous"`**:** a size (`nrow(data)` - `p` x M) matrix containing the exogenous transition weights as `[t, m]` for time t and regime m. Each row needs to sum to one and only weakly positive values are allowed.

cond_dist
specifies the conditional distribution of the model as `"Gaussian"`, `"Student"`, `"ind_Student"`, or `"ind_skewed_t"`, where `"ind_Student"` the Student's t distribution with independent components, and `"ind_skewed_t"` is the skewed t distribution with independent components (see Hansen, 1994).

parametrization
`"intercept"` or `"mean"` determining whether the model is parametrized with intercept parameters ϕ_m or regime means μ_m, m=1,...,M.

AR_constraints a size $(Mpd^2 \times q)$ constraint matrix C specifying linear constraints to the autoregressive parameters. The constraints are of the form $(\varphi_1, ..., \varphi_M) = C\psi$, where $\varphi_m = (vec(A_{m,1}), ..., vec(A_{m,p}))$ $(pd^2 \times 1)$, $m = 1, ..., M$, contains the coefficient matrices and ψ $(q \times 1)$ contains the related parameters. For example, to restrict the AR-parameters to be the identical across the regimes, set $C = [I : ... : I]$' $(Mpd^2 \times pd^2)$ where `I = diag(p*d^2)`.

mean_constraints
Restrict the mean parameters of some regimes to be identical? Provide a list of numeric vectors such that each numeric vector contains the regimes that should share the common mean parameters. For instance, if M=3, the argument `list(1, 2:3)` restricts the mean parameters of the second and third regime to be identical but the first regime has freely estimated (unconditional) mean. Ignore or set to `NULL` if mean parameters should not be restricted to be the same among any regimes. This constraint is available only for mean parametrized models; that is, when `parametrization="mean"`.

weight_constraints
a list of two elements, R in the first element and r in the second element, specifying linear constraints on the transition weight parameters α. The constraints are of the form $\alpha = R\xi + r$, where R is a known $(a \times l)$ constraint matrix of full column rank (a is the dimension of α), r is a known $(a \times 1)$ constant, and ξ is an unknown $(l \times 1)$ parameter. **Alternatively**, set $R = 0$ to constrain the weight parameters to the constant r (in this case, α is dropped from the constrained parameter vector).

ngen
a positive integer specifying the number of generations to be ran through in the genetic algorithm.

popsize
a positive even integer specifying the population size in the genetic algorithm. Default is `10*n_params`.

smart_mu
a positive integer specifying the generation after which the random mutations in the genetic algorithm are "smart". This means that mutating individuals will mostly mutate fairly close (or partially close) to the best fitting individual (which has the least regimes with time varying mixing weights practically at zero) so far.

initpop
a list of parameter vectors from which the initial population of the genetic algorithm will be generated from. The parameter vectors hould have the form $\theta = (\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \sigma, \alpha, \nu)$, where (see exceptions below):

- ϕ_m = the $(d \times 1)$ intercept (or mean) vector of the mth regime.

- $\varphi_m = (vec(A_{m,1}), ..., vec(A_{m,p}))\ (pd^2 \times 1)$.
- **if** `cond_dist="Gaussian"` **or** `"Student"`**:** $\sigma = (vech(\Omega_1), ..., vech(\Omega_M))$ $(Md(d+1)/2 \times 1)$.

    if `cond_dist="ind_Student"` **or** `"ind_skewed_t"`**:** $\sigma = (vec(B_1), ..., vec(B_M))$ $(Md^2 \times 1)$.
- $\alpha =$ the $(a \times 1)$ vector containing the transition weight parameters (see below).
- **if** `cond_dist = "Gaussian"`)**:** Omit ν from the parameter vector.

    if `cond_dist="Student"`**:** $\nu > 2$ is the single degrees of freedom parameter.

    if `cond_dist="ind_Student"`**:** $\nu = (\nu_1, ..., \nu_d)\ (d \times 1)$, $\nu_i > 2$.

    if `cond_dist="ind_skewed_t"`**:** $\nu = (\nu_1, ..., \nu_d, \lambda_1, ..., \lambda_d)\ (2d \times 1)$, $\nu_i > 2$ and $\lambda_i \in (0, 1)$.

For models with...

`weight_function="relative_dens"`**:** $\alpha = (\alpha_1, ..., \alpha_{M-1})\ (M-1 \times 1)$, where $\alpha_m\ (1 \times 1)$, $m = 1, ..., M-1$ are the transition weight parameters.

`weight_function="logistic"`**:** $\alpha = (c, \gamma)\ (2 \times 1)$, where $c \in \mathbb{R}$ is the location parameter and $\gamma > 0$ is the scale parameter.

`weight_function="mlogit"`**:** $\alpha = (\gamma_1, ..., \gamma_M)\ ((M-1)k \times 1)$, where γ_m $(k \times 1)$, $m = 1, ..., M-1$ contains the multinomial logit-regression coefficients of the mth regime. Specifically, for switching variables with indices in $I \subset \{1, ..., d\}$, and with $\tilde{p} \in \{1, ..., p\}$ lags included, γ_m contains the coefficients for the vector $z_{t-1} = (1, \tilde{z}_{\min\{I\}}, ..., \tilde{z}_{\max\{I\}})$, where $\tilde{z}_i = (y_{it-1}, ..., y_{it-\tilde{p}})$, $i \in I$. So $k = 1 + |I|\tilde{p}$ where $|I|$ denotes the number of elements in I.

`weight_function="exponential"`**:** $\alpha = (c, \gamma)\ (2 \times 1)$, where $c \in \mathbb{R}$ is the location parameter and $\gamma > 0$ is the scale parameter.

`weight_function="threshold"`**:** $\alpha = (r_1, ..., r_{M-1})\ (M - 1 \times 1)$, where $r_1, ..., r_{M-1}$ are the threshold values.

`weight_function="exogenous"`**:** Omit α from the parameter vector.

AR_constraints: Replace $\varphi_1, ..., \varphi_M$ with ψ as described in the argument `AR_constraints`.

mean_constraints: Replace $\phi_1, ..., \phi_M$ with $(\mu_1, ..., \mu_g)$ where μ_i, $(d \times 1)$ is the mean parameter for group i and g is the number of groups.

weight_constraints: If linear constraints are imposed, replace α with ξ as described in the argument `weigh_constraints`. If weight functions parameters are imposed to be fixed values, simply drop α from the parameter vector.

Above, ϕ_m is the intercept parameter, $A_{m,i}$ denotes the ith coefficient matrix of the mth regime, Ω_m denotes the positive definite error term covariance matrix of the mth regime, and B_m is the invertible $(d \times d)$ impact matrix of the mth regime. ν_m is the degrees of freedom parameter of the mth regime. If `parametrization=="mean"`, just replace each ϕ_m with regimewise mean μ_m. $vec()$ is vectorization operator that stacks columns of a given matrix into a vector. $vech()$ stacks columns of a given matrix from the principal diagonal downwards (including elements on the diagonal) into a vector.

mu_scale	a size $(d \times 1)$ vector defining **means** of the normal distributions from which each mean parameter μ_m is drawn from in random mutations. Default is colMeans(data). Note that mean-parametrization is always used for optimization in GAfit - even when parametrization=="intercept". However, input (in initpop) and output (return value) parameter vectors can be intercept-parametrized.
mu_scale2	a size $(d \times 1)$ strictly positive vector defining **standard deviations** of the normal distributions from which each mean parameter μ_m is drawn from in random mutations. Default is vapply(1:d, function(i1) sd(data[,i1]), numeric(1)).
omega_scale	a size $(d \times 1)$ strictly positive vector specifying the scale and variability of the random covariance matrices in random mutations. The covariance matrices are drawn from (scaled) Wishart distribution. Expected values of the random covariance matrices are diag(omega_scale). Standard deviations of the diagonal elements are sqrt(2/d)*omega_scale[i] and for non-diagonal elements they are sqrt(1/d*omega_scale[i]*omega_scale[j]). Note that for d>4 this scale may need to be chosen carefully. Default in GAfit is var(stats::ar(data[,i], order.max=10)$resid, na.rm=TRUE), i=1,...,d. This argument is ignored if cond_dist == "ind_Student".
B_scale	a size $(d \times 1)$ strictly positive vector specifying the mean and variability of the random impact matrices in random mutations. In Regime 1, the mean of the error term covariance matrix implied by the random impact matrix will be 0.95*diag(B_scale) and in the rest of the regimes diag(B_scale), whereas the variability increases with B_scale. Default in GAfit is var(stats::ar(data[,i], order.max=10)$resid, na.rm=TRUE), i=1,...,d. This argument is ignored if cond_dist != "ind_Student".
weight_scale	For...
	weight_function %in% c("relative_dens", "exogenous"): not used.
	weight_function %in% c("logistic", "exponential"): length three vector with the mean (in the first element) and standard deviation (in the second element) of the normal distribution the location parameter is drawn from in random mutations. The third element is the standard deviation of the normal distribution from whose absolute value the location parameter is drawn from.
	weight_function == "mlogit": length two vector with the mean (in the first element) and standard deviation (in the second element) of the normal distribution the coefficients of the logit sub model's constant terms are drawn from in random mutations. The third element is the standard deviation of the normal distribution from which the non-constant regressors' coefficients are drawn from.
	weight_function == "threshold": a lenght two vector with the lower bound, in the first element and the upper bound, in the second element, of the uniform distribution threshold parameters are drawn from in random mutations.
ar_scale	a positive real number between zero and one adjusting how large AR parameter values are typically proposed in construction of the initial population: larger value implies larger coefficients (in absolute value). After construction of the initial population, a new scale is drawn from (0, upper_ar_scale) uniform distribution in each iteration.

upper_ar_scale   the upper bound for ar_scale parameter (see above) in the random mutations. Setting this too high might lead to failure in proposing new parameters that are well enough inside the parameter space, and especially with large p one might want to try smaller upper bound (e.g., 0.5). With large p or d, upper_ar_scale is restricted from above, see the details section.

ar_scale2   a positive real number adjusting how large AR parameter values are typically proposed in some random mutations (if AR constraints are employed, in all random mutations): larger value implies **smaller** coefficients (in absolute value). **Values larger than 1 can be used if the AR coefficients are expected to be very small. If set smaller than 1, be careful as it might lead to failure in the creation of parameter candidates that satisfy the stability condition.**

regime_force_scale
                  a non-negative real number specifying how much should natural selection favor individuals with less regimes that have almost all mixing weights (practically) at zero. Set to zero for no favoring or large number for heavy favoring. Without any favoring the genetic algorithm gets more often stuck in an area of the parameter space where some regimes are wasted, but with too much favouring the best genes might never mix into the population and the algorithm might converge poorly. Default is 1 and it gives $2x$ larger surviving probability weights for individuals with no wasted regimes compared to individuals with one wasted regime. Number 2 would give $3x$ larger probability weights etc.

penalized   Perform penalized LS estimation that minimizes penalized RSS in which estimates close to breaking or not satisfying the usual stability condition are penalized? If TRUE, the tuning parameter is set by the argument penalty_params[2], and the penalization starts when the eigenvalues of the companion form AR matrix are larger than 1 - penalty_params[1].

penalty_params   a numeric vector with two positive elements specifying the penalization parameters: the first element determined how far from the boundary of the stability region the penalization starts (a number between zero and one, smaller number starts penalization closer to the boundary) and the second element is a tuning parameter for the penalization (a positive real number, a higher value penalizes non-stability more).

allow_unstab   If TRUE, estimates not satisfying the stability condition are allowed. Always FALSE if weight_function="relative_dens".

red_criteria   a length 2 numeric vector specifying the criteria that is used to determine whether a regime is redundant (or "wasted") or not. Any regime m which satisfies sum(transitionWeights[,m] > red_criteria[1]) < red_criteria[2]*n_obs will be considered "redundant". One should be careful when adjusting this argument (set c(0, 0) to fully disable the 'redundant regime' features from the algorithm).

bound_by_weights
                  should the parameter space be constrained to areas where the transition weights do allocate enough weights to each regime compared to the number of observations in the regime? See the argument min_obs_coef_ga, and if three-phase estimation is used, **carefully** adjust it to be small enough so that estimates obtained from LS/NLS estimation are not discarded. A smaller number than min_obs_coef of LS/NLS estimation should be used.

min_obs_coef_ga

> if bound_by_weights=TRUE, determines the smallest accepted number of observations (times variables) from each regime relative to the number of parameters in the regime. For models with AR constraints, the number of AR matrix parameters in each regimes is simply assumed to be ncol(AR_constraints)/M. See the source code of the function loglikelihood for further details.

pre_smart_mu_prob

> A number in $[0, 1]$ giving a probability of a "smart mutation" occuring randomly in each iteration before the iteration given by the argument smart_mu.

to_return

> should the genetic algorithm return the best fitting individual which has "positive enough" mixing weights for as many regimes as possible ("alt_ind") or the individual which has the highest log-likelihood in general ("best_ind") but might have more wasted regimes?

minval

> a real number defining the minimum value of the log-likelihood function that will be considered. Values smaller than this will be treated as they were minval and the corresponding individuals will never survive. The default is -(10^(ceiling(log10(n_obs)) + d) - 1).

fixed_params

> a vector containing fixed parameter values for intercept, autoregressive, and weight parameters that should be fixed in the **initial population**. Should have the form: $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$, where
>
> - (ϕ_m = the $(d \times 1)$ intercept vector of the mth regime.
> - $\varphi_m = (vec(A_{m,1}), ..., vec(A_{m,p}))$ $(pd^2 \times 1)$.
> - α vector of the weight parameters.
>
> For models with...
>
> **AR_constraints:** Replace $\varphi_1, ..., \varphi_M$ with ψ as described in the argument AR_constraints.
>
> **weight_constraints:** If linear constraints are imposed, replace α with ξ as described in the argument weigh_constraints. If weight functions parameters are imposed to be fixed values, simply drop α from the parameter vector.
>
> Note that fixed_params should always be in the intercept parametrization (and parametrization="intercept" should always be used). **Passing this argument from fitSTVAR in does not do anything, as it is designed to be used with the three-phase estimation procedure only. Also, this argument does not do anything if the initial population is specified in the argument initpop.**

fixed_params_in_smart_mu

> should the fixed parameters be fixed in the smart mutation phase as well? If TRUE, the fixed parameters stay fixed throughout the whole GA estimation.

seed

> a single value, interpreted as an integer, or NULL, that sets seed for the random number generator in the beginning of the function call. If calling GAfit from fitSTVAR, use the argument seeds instead of passing the argument seed.

Details

Only reduced form models are supported!

The core of the genetic algorithm is mostly based on the description by *Dorsey and Mayer (1995)*. It utilizes a slightly modified version of the individually adaptive crossover and mutation rates

described by *Patnaik and Srinivas (1994)* and employs (50%) fitness inheritance discussed by *Smith, Dike and Stegmann (1995)*.

By "redundant" or "wasted" regimes we mean regimes that have the time varying mixing weights practically at zero for almost all t. A model including redundant regimes would have about the same log-likelihood value without the redundant regimes and there is no purpose to have redundant regimes in a model.

Some of the AR coefficients are drawn with the algorithm by Ansley and Kohn (1986). However, when using large ar_scale with large p or d, numerical inaccuracies caused by the imprecision of the float-point presentation may result in errors or nonstationary AR-matrices. Using smaller ar_scale facilitates the usage of larger p or d. Therefore, we bound upper_ar_scale from above by $1 - pd/150$ when p*d>40 and by 1 otherwise.

Structural models are not supported here, as they are best estimated based on reduced form parameter estimates using the function fitSSTVAR.

Value

Returns the estimated parameter vector which has the form described in initpop, **with the exception** that for models with cond_dist == "ind_Student" or "ind_skewed_t", the parameter vector is parametrized with $B_1, B_2^*, ..., B_M^*$ instead of $B_1, B_2, ..., B_M$, where $B_m^* = B_m - B_1$. Use the function change_parametrization to change back to the original parametrization if desired.

gdpdef	*U.S. real GDP percent change and GDP implicit price deflator percent change*

Description

A dataset containing a quarterly U.S. time series with two components: the percentage change of real GDP and the percentage change of GDP implicit price deflator, covering the period from 1959Q1 - 2019Q4.

Usage

```
gdpdef
```

Format

A numeric matrix of class `'ts'` with 244 rows and 2 columns with one time series in each column:

First column (GDP): The quarterly percent change of real U.S. GDP, from 1959Q1 to 2019Q4, `https://fred.stlouisfed.org/series/GDPC1`.

Second column (GDPDEF): The quarterly percent change of U.S. GDP implicit price deflator, from 1959Q1 to 2019Q4, `https://fred.stlouisfed.org/series/GDPDEF`.

get_hetsked_sstvar	*Switch from two-regime reduced form STVAR model to a structural model identified by heteroskedasticity*

Description

`get_hetsked_sstvar` constructs structural STVAR model identified by heteroskedasticity based on a reduced form STVAR model.

Usage

```
get_hetsked_sstvar(stvar, calc_std_errors = FALSE)
```

Arguments

stvar
        a an object of class `'stvar'`, created by, e.g., `fitSTVAR`, specifying a reduced form or a structural model

calc_std_errors

        Calculate approximate standard errors (based on standard asymptotics)?

Details

The switch is made by simultaneously diagonalizing the two error term covariance matrices with a well known matrix decomposition (Muirhead, 1982, Theorem A9.9) and then normalizing the diagonal of the matrix W positive (which implies positive diagonal of the impact matrix). Models with more that two regimes are not supported because the matrix decomposition does not generally exists for more than two covariance matrices.

Value

Returns an object of class `'stvar'` defining a structural STVAR model identified by heteroskedasticity, with the main diagonal of the impact matrix normalized to be positive.

GFEVD	*Estimate generalized forecast error variance decomposition for structural STVAR models.*

Description

GFEVD estimates generalized forecast error variance decomposition for structural STVAR models.

Usage

```
GFEVD(
  stvar,
  N = 30,
  shock_size = 1,
  initval_type = c("data", "random", "fixed"),
  which_cumulative = numeric(0),
  use_data_shocks = FALSE,
  data_gfevd_pars = c(0, 0.75),
  init_regime = 1,
  init_values = NULL,
  R1 = 250,
  R2 = 250,
  ncores = 2,
  burn_in = 1000,
  exo_weights = NULL,
  seeds = NULL,
  use_parallel = TRUE
)

## S3 method for class 'gfevd'
plot(x, ..., data_shock_pars = NULL)

## S3 method for class 'gfevd'
print(x, ..., digits = 2, N_to_print)
```

Arguments

stvar	an object of class 'stvar', created by, e.g., fitSTVAR or fitSSTVAR.
N	a positive integer specifying the horizon how far ahead should the GFEVD be calculated.
shock_size	What sign and size should be used for all shocks? By the normalization, the conditional covariance matrix of the structural error is an identity matrix.

initval_type	What type initial values are used for estimating the GIRFs that the GFEVD is based on?

"data": Estimate the GIRF for all the possible length p histories in the data.

"random": Estimate the GIRF for several random initial values generated from the a specific regime specified by the argument init_regimes. The number of initial values is set with the argument R2.

"fixed": Estimate the GIRF for the initial values specified with the argument init_values.

which_cumulative

a numeric vector with values in $1, ..., d$ (d=ncol(data)) specifying which the variables for which the impulse responses should be cumulative. Default is none.

use_data_shocks

set TRUE (**recommended**) for a special feature in which for every possible length p history in the data, or a subset of them if so specified in the argument data_gfevd_pars, the GFEVD is estimated for a shock that has the sign and size of the corresponding structural shock recovered from the data. See the details section.

data_gfevd_pars

a length two numeric vector with the following elements determining settings for initval_type="data" and use_data_shocks=TRUE:

1. An integer between 0 and M determining the (dominant) regime for which the GFEVD should be calculated (0 for all regimes).
2. A number between 0.5 and 1 determining how large transition weight a regime should have to be considered dominant in a given time period (i.e., determining which histories are used to calculate the GFEVD if the first element is not 0).

init_regime   an integer in $1, ..., M$ specifying the regime from which the initial values should be generated from (using a simulation procedure with a burn-in period). For models with Gaussian conditional distribution, it is also possible to generate the starting values from the stationary distribution of a regime. See the details section.

init_values   a size [p, d, R2] array specifying the initial values in each slice for each Monte Carlo repetition, where d is the number of time series in the system and R2 is an argument of this function. In each slice, the **last** row will be used as initial values for the first lag, the second last row for second lag etc. If not specified, initial values will be drawn from the regime specified in init_regimes.

R1   the number of repetitions used to estimate GIRF for each initial value.

R2   the number of initial values to be drawn/used if initval_type="random" or "fixed".

ncores   the number CPU cores to be used in parallel computing. Only single core computing is supported if an initial value is specified (and the GIRF won't thus be estimated multiple times).

burn_in   Burn-in period for simulating initial values from a regime.

exo_weights   if weight_function="exogenous", provide a size $(N + 1 \times M)$ matrix of exogenous transition weights for the regimes: [h, m] for the (after-the-impact) period $h - 1$ and regime m weight ([1, m] is for the impact period). Ignored if weight_function != "exogenous".

seeds	a numeric vector containing the random number generator seed for estimation of each GIRF. Should have the length of at least...

- ...nrow(data) – p + 1 if initval_type="data" or use_data_shocks=TRUE.
- ...R2 if initval_type="random".
- ...1 if initval_type="fixed.".

If the length of the vector is greater than what is needed, the extra seeds are dropped from the end of the seeds vector. Set to NULL for not initializing the seed.

use_parallel	employ parallel computing? If FALSE, does not print anything.
x	object of class 'gfevd' generated by the function GFEVD.
...	graphical parameters passed to the 'ts' plot method when using data_shock_pars.
data_shock_pars	

if use_data_shocks, alternative plot method can be used that plots the relative contribution of a given shock to the forecast error variance of each variable at a given horizon. Should be a length two numeric vector with the number of the shock (1,..,d) in the first element and the horizon (0,1,2,...,N) in the second element.

digits	the number of decimals to print
N_to_print	an integer specifying the horizon how far to print the estimates. The default is that all the values are printed.

Details

The GFEVD is a forecast error variance decomposition calculated with the generalized impulse response function (GIRF). See Lanne and Nyberg (2016) for details.

If use_data_shocks=TRUE, each GIRF in the GFEVD is estimated for a shock that has the sign and size of the corresponding structural shock recovered from the fitted model. This is done for every possible length p history in the data, or to a subset of the histories based in the settings given in the argument data_gfevd_pars. The GFEVD is then calculated as the average of the GFEVDs obtained from the GIRFs estimated for the data shocks. The plot and print methods can be used as usual for this GFEVD, but there is also a special feature that allows to plot the contribution of each shock to the variance of the forecast errors at various horizons in specific historical points of time. This can be done by using the plot method with the argument data_shock_pars. Note that the arguments shock_size, initval_type, and init_regime are ignored if use_data_shocks=TRUE.

Value

Returns and object of class 'gfevd' containing the GFEVD for all the variables and to the transition weights. Note that the decomposition does not exist at horizon zero for transition weights because the related GIRFs are always zero at impact. Also contains the individual GFEVDs for each used initial length p initial value (history) as 4D array with dimensions [horizon, variable, shock, time].

Functions

- plot(gfevd): plot method
- print(gfevd): print method

GIRF   *Estimate generalized impulse response function for structural STVAR*
                                models.

Description

GIRF estimates generalized impulse response function for structural STVAR models.

Usage

```
GIRF(
  stvar,
  which_shocks,
  shock_size = 1,
  N = 30,
  R1 = 250,
  R2 = 250,
  init_regime = 1,
  init_values = NULL,
  which_cumulative = numeric(0),
  scale = NULL,
  scale_type = c("instant", "peak"),
  scale_horizon = N,
  ci = c(0.95, 0.8),
  use_data_shocks = FALSE,
  data_girf_pars = c(0, 0.75, 0, 0, 1.5),
  ncores = 2,
  burn_in = 1000,
  exo_weights = NULL,
  seeds = NULL,
  use_parallel = TRUE
)
```

```
## S3 method for class 'girf'
plot(x, margs, ...)

## S3 method for class 'girf'
print(x, ..., digits = 2, N_to_print)
```

Arguments

stvar	an object of class 'stvar', created by, e.g., fitSTVAR or fitSSTVAR.
which_shocks	a numeric vector of length at most d (=ncol(data)) and elements in $1, ..., d$ specifying the structural shocks for which the GIRF should be estimated.
shock_size	a non-zero scalar value specifying the common size for all scalar components of the structural shock. Note that the conditional covariance matrix of the structural shock is normalized to an identity matrix and that the (generalized) impulse responses may not be symmetric with respect to the sign and size of the shock.
N	a positive integer specifying the horizon how far ahead should the generalized impulse responses be calculated.
R1	the number of repetitions used to estimate GIRF for each initial value.
R2	the number of initial values to use, i.e., to draw from init_regime if init_values are not specified. The confidence bounds will be sample quantiles of the GIRFs based on different initial values. Ignored if the argument init_value is specified. @param init_regime an integer in $1, ..., M$ specifying the regime from which the initial values should be generated from (see ?simulate.stvar). If use_data_shocks=TRUE this is argument not used and data_girf_pars should be specified instead.
init_regime	an integer in $1, ..., M$ specifying the regime from which the initial values should be generated from (using a simulation procedure with a burn-in period). For models with Gaussian conditional distribution, it is also possible to generate the starting values from the stationary distribution of a regime. See the details section.
init_values	a size [p, d, R2] array specifying the initial values in each slice for each Monte Carlo repetition, where d is the number of time series in the system and R2 is an argument of this function. In each slice, the **last** row will be used as initial values for the first lag, the second last row for second lag etc. If not specified, initial values will be drawn from the regime specified in init_regimes.
which_cumulative	
	a numeric vector with values in $1, ..., d$ (d=ncol(data)) specifying which the variables for which the impulse responses should be cumulative. Default is none.
scale	should the GIRFs to some of the shocks be scaled so that they correspond to a specific magnitude of instantaneous or peak response of some specific variable (see the argument scale_type)? Provide a length three vector where the shock of interest is given in the first element (an integer in $1, ..., d$), the variable of interest is given in the second element (an integer in $1, ..., d$), and the magnitude of its instantaneous or peak response in the third element (a non-zero real number). If the GIRFs of multiple shocks should be scaled, provide a matrix which has one column for each of the shocks with the columns being the length three vectors described above.

scale_type	If argument `scale` is specified, should the GIRFs be scaled to match an instantaneous response (`"instant"`) or peak response (`"peak"`). If `"peak"`, the scale is based on the largest magnitude of peak response in absolute value. Ignored if `scale` is not specified.
scale_horizon	If `scale_type == "peak"` what the maximum horizon up to which peak response is expected? Scaling won't based on values after this.
ci	a numeric vector with elements in $(0, 1)$ specifying the confidence levels of the "confidence intervals" that **do not** quantify uncertainty about the true parameter value but only uncertainty about the initial value (and possibly sign and size of the shock) within the given regime.
use_data_shocks	
	set TRUE for a special feature in which for every possible length p history in the data, or a subset of them if so specified in the argument `data_girf_pars`, the GIRF is estimated for a shock that has the sign and size of the corresponding structural shock recovered from the data. If used, the argument `which_shocks` must specify only one shock. See the details section.
data_girf_pars	a length five numeric vector with the following elements determining settings for `use_data_shocks=TRUE` (concerns the single shock specified in the argument `which_shocks`):

1. An integer between `0` and `M` determining the (dominant) regime for which the GIRF should be calculated (`0` for all regimes).
2. A number between `0.5` and `1` determining how large transition weight a regime should have to be considered dominant in a given time period (i.e., determining which histories are used to calculate the GIRF if the first element is not `0`).
3. Either `0`, `-1`, or `1`, determining whether the GIRF should be calculated using shocks of all signs, only negative shocks, or only positive shocks, respectively.
4. Either, `0`, `1`, or `2`, determining whether the GIRF should be calculated using shocks of all sizes, only small shocks, or only large shocks, respectively.
5. A strictly positive real number determining what size shocks are considered large and what size small "in the scale of standard deviations" (for example, if set to 2, shocks larger than that are considered large and shocks smaller than that are considered small; note that the standard deviations of the shocks are normalized to unity).

ncores	the number CPU cores to be used in parallel computing. Only single core computing is supported if an initial value is specified (and the GIRF won't thus be estimated multiple times).
burn_in	Burn-in period for simulating initial values from a regime.
exo_weights	if `weight_function="exogenous"`, provide a size $(N + 1 \times M)$ matrix of exogenous transition weights for the regimes: `[h, m]` for the (after-the-impact) period $h - 1$ and regime m weight (`[1, m]` is for the impact period). Ignored if `weight_function != "exogenous"`.
seeds	A numeric vector initializing the seeds for the random number generator for estimation of each GIRF. Should have the length of at least (extra seeds are removed from the end of the vector)...

> **If initial values are drawn using** init_regime: R2
>
> **If initial values are specified in** init_values: dim(init_values)[3]
>
> **If** use_data_shocks=TRUE: 1 (the vector of seeds are generated according on the number of histories in the data that satisfy the conditions given in the argument data_girf_pars).
>
> Set NULL for not initializing the seed.

use_parallel	employ parallel computing? If FALSE, does not print anything.
x	object of class 'girf' generated by the function GIRF.
margs	numeric vector of length four that adjusts the [bottom_marginal, left_marginal, top_marginal, right_marginal] as the relative sizes of the marginals to the figures of the responses.
...	graphical parameters passed to plot method plotting the GIRFs
digits	the number of decimals to print
N_to_print	an integer specifying the horizon how far to print the estimates and confidence intervals. The default is that all the values are printed.

Details

The "confidence bounds" **do not** quantify uncertainty about the true parameter value but only the initial values (and possibly sign and size of the shock) within the given regime. If initial values are specified, confidence intervals won't be calculated. Note that if the bounds look weird in the figure produced by plot.girf, it is probably because the point estimate is not inside the bounds. In this case, increasing the argument R2 usually fixes the issue.

Note that if the argument scale is used, the scaled responses of the transition weights might be more than one in absolute value.

If weight_function="exogenous", exogenous transition weights used in the Monte Carlo simulations for the future sample paths of the process must the given in the argument exo_weights. The same weights are used as the transition weights across the Monte Carlo repetitions.

If use_data_shocks=TRUE, the GIRF is estimated using all, or a subset of, the length p histories in the data as the initial values, and using the sign and size of the corresponding structural shock recovered from the fitted model. The subset of the length p histories are determined based in the settings given in the argument data_girf_pars. Note that the arguments shock_size and init_regime are ignored if use_data_shocks=TRUE.

Value

Returns a class 'girf' list with the GIRFs in the first element ($girf_res) and the used arguments the rest. The first element containing the GIRFs is a list with the mth element containing the point estimates for the GIRF in $point_est (the first element) and confidence intervals in $conf_ints (the second element). The first row is for the GIRF at impact ($n = 0$), the second for $n = 1$, the third for $n = 2$, and so on.

The element $all_girfs is a list containing results from all the individual GIRFs obtained from the MC repetitions. Each element is for one shock and results are in array of the form [horizon, variables, MC-repetitions].

Functions

- plot(girf): plot method
- print(girf): print method

---

hist_decomp   *Compute historical decompositions for structural STVAR models.*

Description

hist_decomp computes historical decompositions for structural STVAR models.

Usage

```
hist_decomp(stvar)

## S3 method for class 'histdecomp'
plot(x, ..., plot_by_shock = FALSE, which_to_plot)

## S3 method for class 'histdecomp'
print(x, ..., digits = 3, which_vars, which_indices)
```

Arguments

stvar	an object of class 'stvar' defining a structural or reduced form STVAR model. For a reduced form model (that is not readily identified statiscally), the shocks are automatically identified by the lower triangular Cholesky decomposition.
x	object of class 'histdecomp' created by the function hist_decomp.
...	currently not in use.
plot_by_shock	should the historical decompositions by plotted so that there is one figure for each shock (rather than one figure for each variable)?
which_to_plot	a numeric vector with the indices of the variables or shocks (depending on the argument plot_by_shock) to be plotted. The default is to plot all of them.
digits	how many significant digits to print?
which_vars	a numeric vector specifying the variables to print. The default is that all the variables are printed.
which_indices	a numeric vector specifying the time period indices to print. The default is that all the time periods are printed.

Details

The historical decomposition quantifies the cumulative effects the shocks to the movements of the variables (see, e.g., Kilian and Lütkepohl, 2017, Section~4.3) The historical decompositions are computed as described in Wong (2018). Note that due to the effect of the "initial conditions" and the "steady state component", which are not attributed to the shocks, the cumulative effects of the shocks do not sum to the observed time series.

Value

Returns a class `'histdecomp'` list with the following elements:

init_cond_comp A matrix of size $(T \times d)$ containing the contributions of the initial conditions to the movements of the variables at each time point; the element `t, i` giving the contribution at the time `t` on the variable `i`.

steady_state_comp A matrix of size $(T \times d)$ containing the contributions of the steady state component to the movements of the variables at each time point; the element `t, i` giving the contribution at the time `t` on the variable `i`.

shock_comp A matrix of size $(T \times d)$ containing the contributions of the shocks to the movements of the variables at each time point; the element `t, i` giving the contribution at the time `t` on the variable `i`.

contributions_of_shocks A 3D array of size $(T \times d \times d)$ containing the cumulative contributions of the shocks to the movements of the variables at each time point; the element `t, i1, i2` giving the contribution of the shock `i1` to the variable `i2` at the time `t`.

stvar The original STVAR model object.

Returns the input object x invisibly.

Functions

- `plot(histdecomp)`: plot method
- `print(histdecomp)`: print method

in_paramspace *Determine whether the parameter vector is in the parameter space*

Description

`in_paramspace` checks whether the parameter vector is in the parameter space.

Usage

```
in_paramspace(
  p,
  M,
  d,
  params,
 weight_function = c("relative_dens", "logistic", "mlogit", "exponential", "threshold",
    "exogenous"),
  weightfun_pars = NULL,
  cond_dist = c("Gaussian", "Student", "ind_Student", "ind_skewed_t"),
  identification = c("reduced_form", "recursive", "heteroskedasticity",
    "non-Gaussianity"),
  B_constraints = NULL,
  other_constraints = NULL,
  all_boldA,
  all_Omegas,
  weightpars,
  distpars,
```

```
    transition_weights,
    allow_unstab = FALSE,
    stab_tol = 0.001,
    posdef_tol = 1e-08,
    distpar_tol = 1e-08,
    weightpar_tol = 1e-08
)
```

Arguments

p	a positive integer specifying the autoregressive order
M	a positive integer specifying the number of regimes
d	the number of time series in the system, i.e., the dimension
params	a real valued vector specifying the parameter values. Should have the form $\theta = (\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \sigma, \alpha, \nu)$, where (see exceptions below):

- $\phi_m =$ the $(d \times 1)$ intercept (or mean) vector of the mth regime.
- $\varphi_m = (vec(A_{m,1}), ..., vec(A_{m,p})) \ (pd^2 \times 1)$.
- **if** cond_dist="Gaussian" **or** "Student": $\sigma = (vech(\Omega_1), ..., vech(\Omega_M))$ $(Md(d+1)/2 \times 1)$.

  if cond_dist="ind_Student" **or** "ind_skewed_t": $\sigma = (vec(B_1), ..., vec(B_M))$ $(Md^2 \times 1)$.
- $\alpha =$ the $(a \times 1)$ vector containing the transition weight parameters (see below).
- **if** cond_dist = "Gaussian"): Omit ν from the parameter vector.

  if cond_dist="Student": $\nu > 2$ is the single degrees of freedom parameter.

  if cond_dist="ind_Student": $\nu = (\nu_1, ..., \nu_d) \ (d \times 1), \nu_i > 2$.

  if cond_dist="ind_skewed_t": $\nu = (\nu_1, ..., \nu_d, \lambda_1, ..., \lambda_d) \ (2d \times 1), \nu_i > 2$ and $\lambda_i \in (0, 1)$.

For models with...

weight_function="relative_dens": $\alpha = (\alpha_1, ..., \alpha_{M-1}) \ (M-1 \times 1)$, where $\alpha_m \ (1 \times 1), m = 1, ..., M-1$ are the transition weight parameters.

weight_function="logistic": $\alpha = (c, \gamma) \ (2 \times 1)$, where $c \in \mathbb{R}$ is the location parameter and $\gamma > 0$ is the scale parameter.

weight_function="mlogit": $\alpha = (\gamma_1, ..., \gamma_M) \ ((M-1)k \times 1)$, where γ_m $(k \times 1), m = 1, ..., M-1$ contains the multinomial logit-regression coefficients of the mth regime. Specifically, for switching variables with indices in $I \subset \{1, ..., d\}$, and with $\tilde{p} \in \{1, ..., p\}$ lags included, γ_m contains the coefficients for the vector $z_{t-1} = (1, \tilde{z}_{\min\{I\}}, ..., \tilde{z}_{\max\{I\}})$, where $\tilde{z}_i = (y_{it-1}, ..., y_{it-\tilde{p}}), i \in I$. So $k = 1 + |I|\tilde{p}$ where $|I|$ denotes the number of elements in I.

weight_function="exponential": $\alpha = (c, \gamma) \ (2 \times 1)$, where $c \in \mathbb{R}$ is the location parameter and $\gamma > 0$ is the scale parameter.

weight_function="threshold": $\alpha = (r_1, ..., r_{M-1}) \ (M-1 \times 1)$, where $r_1, ..., r_{M-1}$ are the thresholds.

`weight_function="exogenous"`: Omit α from the parameter vector.

AR_constraints: Replace $\varphi_1, ..., \varphi_M$ with ψ as described in the argument `AR_constraints`.

mean_constraints: Replace $\phi_1, ..., \phi_M$ with $(\mu_1, ..., \mu_g)$ where $\mu_i, \; (d \times 1)$ is the mean parameter for group i and g is the number of groups.

weight_constraints: If linear constraints are imposed, replace α with ξ as described in the argument `weigh_constraints`. If weight functions parameters are imposed to be fixed values, simply drop α from the parameter vector.

`identification="heteroskedasticity"`: $\sigma = (vec(W), \lambda_2, ..., \lambda_M)$, where $W \; (d \times d)$ and $\lambda_m \; (d \times 1)$, $m = 2, ..., M$, satisfy $\Omega_1 = WW'$ and $\Omega_m = W\Lambda_m W'$, $\Lambda_m = diag(\lambda_{m1}, ..., \lambda_{md})$, $\lambda_{mi} > 0$, $m = 2, ..., M$, $i = 1, ..., d$.

B_constraints: For models identified by heteroskedasticity, replace $vec(W)$ with $\tilde{vec}(W)$ that stacks the columns of the matrix W in to vector so that the elements that are constrained to zero are not included. For models identified by non-Gaussianity, replace $vec(B_1), ..., vec(B_M)$ with similarly with vectorized versions B_m so that the elements that are constrained to zero are not included.

Above, ϕ_m is the intercept parameter, $A_{m,i}$ denotes the ith coefficient matrix of the mth regime, Ω_m denotes the positive definite error term covariance matrix of the mth regime, and B_m is the invertible $(d \times d)$ impact matrix of the mth regime. ν_m is the degrees of freedom parameter of the mth regime. If `parametrization=="mean"`, just replace each ϕ_m with regimewise mean μ_m. $vec()$ is vectorization operator that stacks columns of a given matrix into a vector. $vech()$ stacks columns of a given matrix from the principal diagonal downwards (including elements on the diagonal) into a vector. $Bvec()$ is a vectorization operator that stacks the columns of a given impact matrix B_m into a vector so that the elements that are constrained to zero by the argument `B_constraints` are excluded.

`weight_function`

What type of transition weights $\alpha_{m,t}$ should be used?

`"relative_dens"`: $\alpha_{m,t} = \frac{\alpha_m f_{m,dp}(y_{t-1},...,y_{t-p+1})}{\sum_{n=1}^{M} \alpha_n f_{n,dp}(y_{t-1},...,y_{t-p+1})}$, where $\alpha_m \in (0,1)$ are weight parameters that satisfy $\sum_{m=1}^{M} \alpha_m = 1$ and $f_{m,dp}(\cdot)$ is the dp-dimensional stationary density of the mth regime corresponding to p consecutive observations. Available for Gaussian conditional distribution only.

`"logistic"`: $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = [1 + \exp\{-\gamma(y_{it-j} - c)\}]^{-1}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

`"mlogit"`: $\alpha_{m,t} = \frac{\exp\{\gamma_m' z_{t-1}\}}{\sum_{n=1}^{M} \exp\{\gamma_n' z_{t-1}\}}$, where γ_m are coefficient vectors, $\gamma_M = 0$, and $z_{t-1} \; (k \times 1)$ is the vector containing a constant and the (lagged) switching variables.

`"exponential"`: $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = 1 - \exp\{-\gamma(y_{it-j} - c)\}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

`"threshold"`: $\alpha_{m,t} = 1$ if $r_{m-1} < y_{it-j} \leq r_m$ and 0 otherwise, where $-\infty \equiv r_0 < r_1 < \cdots < r_{M-1} < r_M \equiv \infty$ are thresholds y_{it-j} is the lag j

observation of the ith variable.

"exogenous": Exogenous nonrandom transition weights, specify the weight series in weightfun_pars.

See the vignette for more details about the weight functions.

weightfun_pars   **If** weight_function == "relative_dens": Not used.

If weight_function %in% c("logistic", "exponential", "threshold"): a numeric vector with the switching variable $i \in \{1, ..., d\}$ in the first and the lag $j \in \{1, ..., p\}$ in the second element.

If weight_function == "mlogit": a list of two elements:

The first element $vars: a numeric vector containing the variables that should used as switching variables in the weight function in an increasing order, i.e., a vector with unique elements in $\{1, ..., d\}$.

The second element $lags: an integer in $\{1, ..., p\}$ specifying the number of lags to be used in the weight function.

If weight_function == "exogenous": a size (nrow(data) - p x M) matrix containing the exogenous transition weights as [t, m] for time t and regime m. Each row needs to sum to one and only weakly positive values are allowed.

cond_dist   specifies the conditional distribution of the model as "Gaussian", "Student", "ind_Student", or "ind_skewed_t", where "ind_Student" the Student's t distribution with independent components, and "ind_skewed_t" is the skewed t distribution with independent components (see Hansen, 1994).

identification   is it reduced form model or an identified structural model; if the latter, how is it identified (see the vignette or the references for details)?

"reduced_form": Reduced form model.

"recursive": The usual lower-triangular recursive identification of the shocks via their impact responses.

"heteroskedasticity": Identification by conditional heteroskedasticity, which imposes constant relative impact responses for each shock.

"non-Gaussianity": Identification by non-Gaussianity; requires mutually independent non-Gaussian shocks, thus, currently available only with the conditional distribution "ind_Student".

B_constraints   a $(d \times d)$ matrix with its entries imposing constraints on the impact matrix B_t: NA indicating that the element is unconstrained, a positive value indicating strict positive sign constraint, a negative value indicating strict negative sign constraint, and zero indicating that the element is constrained to zero. Currently only available for models with identification="heteroskedasticity" or "non-Gaussianity" due to the (in)availability of appropriate parametrizations that allow such constraints to be imposed.

other_constraints

A list containing internally used additional type of constraints (see the options below).

$fixed_lambdas (only if identification="heteroskedasticity"): a length $d(M-1)$ numeric vector $(\lambda_2, ..., \lambda_M)$ with elements strictly larger than zero specifying the fixed parameter values for the parameters λ_{mi} should be constrained to.

$B1_constraints (only if `identification="non-Gaussianity"`): set to the string "fixed_sign_and_order" to impose the constraints that the elements of the first impact matrix B_1 are strictly positive and that they are in a decreasing order.

`all_boldA`	3D array containing the $((dp)x(dp))$ "bold A" (companion form) matrices of each regime, obtained from `form_boldA`. Will be computed if not given.
`all_Omegas`	A 3D array containing the covariance matrix parameters obtain from `pick_Omegas`...

    If `cond_dist %in% c("Gaussian", "Student")`: all covariance matrices Ω_m in `[, , m]`.

    If `cond_dist=="ind_Student"`: all impact matrices B_m of the regimes in `[, , m]`.

`weightpars`	numerical vector containing the transition weight parameters, obtained from `pick_weightpars`.
`distpars`	A numeric vector containing the distribution parameters...

    If `cond_dist=="Gaussian"`: Not used, i.e., a numeric vector of length zero.

    If `cond_dist=="Student"`: The degrees of freedom parameter, i.e., a numeric vector of length one.

`transition_weights`

    (optional; only for models with `cond_dist="ind_Student"` or `identification="non-Gaussianity"`) A $T \times M$ matrix containing the transition weights. If `cond_dist="ind_Student"` checks that the impact matrix $\sum_{m=1}^{M} \alpha_{m,t}^{1/2} B_m$ is invertible for all $t = 1, ..., T$.

`allow_unstab`	If `TRUE`, estimates not satisfying the stability condition are allowed. Always `FALSE` if `weight_function="relative_dens"`.
`stab_tol`	numerical tolerance for stability of condition of the regimes: if the "bold A" matrix of any regime has eigenvalues larger that `1 - stat_tol` the parameter is considered to be outside the parameter space. Note that if tolerance is too small, numerical evaluation of the log-likelihood might fail and cause error.
`posdef_tol`	numerical tolerance for positive definiteness of the error term covariance matrices: if the error term covariance matrix of any regime has eigenvalues smaller than this, the parameter is considered to be outside the parameter space. Note that if the tolerance is too small, numerical evaluation of the log-likelihood might fail and cause error.
`distpar_tol`	the parameter vector is considered to be outside the parameter space if the degrees of freedom parameters is not larger than `2 + distpar_tol` (applies only if `cond_dist="Student"`).
`weightpar_tol`	numerical tolerance for weight parameters being in the parameter space. Values closer to to the border of the parameter space than this are considered to be "outside" the parameter space.

Details

The parameter vector in the argument `params` should be unconstrained and reduced form.

Value

Returns `TRUE` if the given parameter values are in the parameter space and `FALSE` otherwise. This function does NOT consider identification conditions!

iterate_more	*Maximum likelihood estimation of a reduced form or structural STVAR model based on preliminary estimates*

Description

`iterate_more` uses a variable metric algorithm to estimate a reduced form or structural STVAR model (object of class `'stvar'`) based on preliminary estimates.

Usage

```
iterate_more(
  stvar,
  maxit = 1000,
  h = 0.001,
  penalized,
  penalty_params,
  allow_unstab,
  calc_std_errors = TRUE,
  print_trace = TRUE
)
```

Arguments

stvar	an object of class `'stvar'`, created by, e.g., `fitSTVAR` or `fitSSTVAR`.
maxit	the maximum number of iterations in the variable metric algorithm.
h	the step size used in the central difference approximation of the gradient of the log-likelihood function, so h should be a small positive real number.
penalized	should penalized log-likelihood function be used that penalizes the log-likelihood function when the parameter values are close the boundary of the stability region or outside it? If `TRUE`, estimates that do not satisfy the stability condition are allowed (except when `weight_function="relative_dens"`). The default is `TRUE` for three-phase estimation and `FALSE` for two-phase estimation.

penalty_params   a numeric vector with two positive elements specifying the penalization parameters: the first element determined how far from the boundary of the stability region the penalization starts (a number between zero and one, smaller number starts penalization closer to the boundary) and the second element is a tuning parameter for the penalization (a positive real number, a higher value penalizes non-stability more).

allow_unstab   If TRUE, estimates not satisfying the stability condition are allowed. Always FALSE if weight_function="relative_dens".

calc_std_errors
   Calculate approximate standard errors (based on standard asymptotics)?

print_trace   should the trace of the optimization algorithm be printed?

Details

The purpose of iterate_more is to provide a simple and convenient tool to finalize the estimation when the maximum number of iterations is reached when estimating a STVAR model with the main estimation function fitSTVAR or fitSSTVAR.

Value

Returns an S3 object of class 'stvar' defining a smooth transition VAR model. The returned list contains the following components (some of which may be NULL depending on the use case):

data   The input time series data.

model   A list describing the model structure.

params   The parameters of the model.

std_errors   Approximate standard errors of the parameters, if calculated.

transition_weights
   The transition weights of the model.

regime_cmeans   Conditional means of the regimes, if data is provided.

total_cmeans   Total conditional means of the model, if data is provided.

total_ccovs   Total conditional covariances of the model, if data is provided.

uncond_moments   A list of unconditional moments including regime autocovariances, variances, and means.

residuals_raw   Raw residuals, if data is provided.

residuals_std   Standardized residuals, if data is provided.

structural_shocks
   Recovered structural shocks, if applicable.

loglik   Log-likelihood of the model, if data is provided.

IC   The values of the information criteria (AIC, HQIC, BIC) for the model, if data is provided.

all_estimates   The parameter estimates from all estimation rounds, if applicable.

all_logliks   The log-likelihood of the estimates from all estimation rounds, if applicable.

which_converged

Indicators of which estimation rounds converged, if applicable.

which_round   Indicators of which round of optimization each estimate belongs to, if applicable.

seeds   The seeds used in the estimation in fitSTVAR, if applicable.

LS_estimates   The least squares estimates of the parameters in the form $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$ (intercepts replaced by unconditional means if mean parametrization is used), if applicable.

Examples

```
## These are long running examples that take approximately 20 seconds to run.

# Estimate two-regime Gaussian STVAR p=1 model with the weighted relative stationary densities
# of the regimes as the transition weight function, but only 5 iterations of the variable matrix
# algorithm:
fit12 <- fitSTVAR(gdpdef, p=1, M=2, nrounds=1, seeds=1, ncores=1, maxit=5)

# The iteration limit was reached, so the estimate is not local maximum.
# The gradient of the log-likelihood function:
get_foc(fit12) # Not close to zero!

# So, we run more iterations of the variable metric algorithm:
fit12 <- iterate_more(fit12)

# The gradient of the log-likelihood function after iterating more:
get_foc(fit12) # Close (enough) to zero!
```

linear_IRF   *Estimate linear impulse response function based on a single regime of a structural STVAR model.*

Description

linear_IRF estimates linear impulse response function based on a single regime of a structural STVAR model.

Usage

```
linear_IRF(
  stvar,
  N = 30,
  regime = 1,
  which_cumulative = numeric(0),
  scale = NULL,
  ci = NULL,
  bootstrap_reps = 100,
  ncores = 2,
  robust_method = c("Nelder-Mead", "SANN", "none"),
  maxit_robust = 1000,
  seed = NULL,
  ...
)

## S3 method for class 'irf'
plot(x, shocks_to_plot, ...)

## S3 method for class 'irf'
print(x, ..., digits = 2, N_to_print, shocks_to_print)
```

Arguments

stvar
: an object of class 'stvar' defining a structural or reduced form STVAR model. For a reduced form model (that is not readily identified statiscally), the shocks are automatically identified by the lower triangular Cholesky decomposition.

N
: a positive integer specifying the horizon how far ahead should the linear impulse responses be calculated.

regime
: Based on which regime the linear IRF should be calculated? An integer in $1, ..., M$.

which_cumulative
: a numeric vector with values in $1, ..., d$ (d=ncol(data)) specifying which the variables for which the linear impulse responses should be cumulative. Default is none.

scale	should the linear IRFs to some of the shocks be scaled so that they correspond to a specific instantaneous response of some specific variable? Provide a length three vector where the shock of interest is given in the first element (an integer in $1, ..., d$), the variable of interest is given in the second element (an integer in $1, ..., d$), and its instantaneous response in the third element (a non-zero real number). If the linear IRFs of multiple shocks should be scaled, provide a matrix which has one column for each of the shocks with the columns being the length three vectors described above.
ci	a real number in $(0, 1)$ specifying the confidence level of the confidence intervals calculated via a fixed-design wild residual bootstrap method. Available only for models that impose linear autoregressive dynamics (excluding changes in the volatility regime).
bootstrap_reps	the number of bootstrap repetitions for estimating confidence bounds.
ncores	the number of CPU cores to be used in parallel computing when bootstrapping confidence bounds.
robust_method	Should some robust estimation method be used in the estimation before switching to the gradient based variable metric algorithm? See details.
maxit_robust	the maximum number of iterations on the first phase robust estimation, if employed.
seed	a real number initializing the seed for the random generator.
...	currently not used.
x	object of class 'irf' generated by the function linear_IRF.
shocks_to_plot	IRFs of which shocks should be plotted? A numeric vector with elements in 1,...,d.
digits	the number of decimals to print
N_to_print	an integer specifying the horizon how far to print the estimates and confidence intervals. The default is that all the values are printed.
shocks_to_print	the responses to which should should be printed? A numeric vector with elements in 1,...,d. The default is that responses to all the shocks are printed.

Details

If the autoregressive dynamics of the model are linear (i.e., either M == 1 or mean and AR parameters are constrained identical across the regimes), confidence bounds can be calculated based on a fixed-design wild residual bootstrap method. We employ the method described in Herwartz and Lütkepohl (2014); see also the relevant chapters in Kilian and Lütkepohl (2017).

Employs the estimation function optim from the package stats that implements the optimization algorithms. The robust optimization method Nelder-Mead is much faster than SANN but can get stuck at a local solution. See ?optim and the references therein for further details.

For model identified by non-Gaussianity, the signs and ordering of the shocks are normalized by assuming that the first non-zero element of each column of the impact matrix of Regime 1 is strictly positive and they are in a decreasing order. Use the argument scale to obtain IRFs scaled for specific impact responses.

Value

Returns a class `'irf'` list with with the following elements:

`$point_est`: a 3D array `[variables, shock, horizon]` containing the point estimates of the IRFs. Note that the first slice is for the impact responses and the slice i+1 for the period i. The response of the variable 'i1' to the shock 'i2' is subsetted as `$point_est[i1, i2, ]`.

`$conf_ints`: bootstrapped confidence intervals for the IRFs in a `[variables, shock, horizon, bound]` 4D array. The lower bound is obtained as `$conf_ints[, , , 1]`, and similarly the upper bound as `$conf_ints[, , , 2]`. The subsetted 3D array is then the bound in a form similar to `$point_est`.

`$all_bootstrap_reps`: IRFs from all of the bootstrap replications in a `[variables, shock, horizon, rep]`. 4D array. The IRF from replication i1 is obtained as `$all_bootstrap_reps[, , , i1]`, and the subsetted 3D array is then the in a form similar to `$point_est`.

Other elements: contains some of the arguments the `linear_IRF` was called with.

Functions

- `plot(irf)`: plot method
- `print(irf)`: print method

```

LR_test   *Perform likelihood ratio test for a STVAR model*

Description

LR_test performs a likelihood ratio test for a STVAR model

Usage

```
LR_test(stvar1, stvar2)
```

Arguments

stvar1	an object of class 'stvar' generated by fitSTVAR or STVAR, containing the **freely estimated** model.
stvar2	an object of class 'stvar' generated by fitSTVAR or STVAR, containing the **constrained** model.

Details

Performs a likelihood ratio test, testing the null hypothesis that the true parameter value lies in the constrained parameter space. Under the null, the test statistic is asymptotically χ^2-distributed with k degrees of freedom, k being the difference in the dimensions of the unconstrained and constrained parameter spaces.

The test is based on the assumption of the standard result of asymptotic normality! Also, note that this function does **not** verify that the two models are actually nested.

Value

A list with class "hypotest" containing the test results and arguments used to calculate the test.

plot.stvarpred   *Predict method for class 'stvar' objects*

Description

predict.stvar is a predict method for class 'stvar' objects.

Usage

```
## S3 method for class 'stvarpred'
plot(x, ..., nt, trans_weights = TRUE)

## S3 method for class 'stvar'
predict(
  object,
  ...,
  nsteps,
  nsim = 1000,
  pi = c(0.95, 0.8),
  pred_type = c("mean", "median"),
  exo_weights = NULL
)

## S3 method for class 'stvarpred'
print(x, ..., digits = 2)
```

Arguments

x	object of class `'stvarpred'`
...	currently not used.
nt	a positive integer specifying the number of observations to be plotted along with the forecast.
trans_weights	should forecasts for transition weights be plotted?
object	an object of class `'stvar'`.
nsteps	how many steps ahead should be predicted?
nsim	to how many independent simulations should the forecast be based on?
pi	a numeric vector specifying the confidence levels of the prediction intervals.
pred_type	should the pointforecast be based on sample "median" or "mean"?
exo_weights	if `weight_function="exogenous"`, provide a size $(nsteps x M)$ matrix of exogenous transition weights for the regimes: `[step, m]` for $step$ steps ahead and regime m weight. Ignored if `weight_function!="exogenous"`.
digits	the number of decimals to print

Details

The forecasts are computed by simulating multiple sample paths of the future observations and using the sample medians or means as point forecasts and empirical quantiles as prediction intervals.

Value

Returns a class 'stvarpred' object containing, among the specifications,...

$pred Point forecasts

$pred_ints Prediction intervals, as `[, , d]`.

$trans_pred Point forecasts for the transition weights

$trans_pred_ints Individual prediction intervals for transition weights, as `[, , m]`, m=1,..,M.

Functions

- `plot(stvarpred)`: predict method
- `print(stvarpred)`: print method

plot_struct_shocks   *Plot structural shock time series of a STVAR model*

Description

plot_struct_shocks plots structural shock time series of a structural STVAR model. For reduced form models (not identified by non-Gaussianity), recursive identification is assumed.

Usage

```
plot_struct_shocks(stvar)
```

Arguments

stvar   object of class `"stvar"`

Details

Plot the time series of the structural shocks of a structural STVAR model.

Value

No return value, called for its side effect of plotting the structural shock time series.

```

Portmanteau_test   *Perform adjusted Portmanteau test for a STVAR model*

Description

`Portmanteau_test` performs adjusted Portmanteau test for remaining autocorrelation (or heteroskedasticity) in the residuals of a STVAR model.

Usage

```
Portmanteau_test(stvar, nlags = 20, which_test = c("autocorr", "het.sked"))
```

Arguments

stvar	an object of class `'stvar'` generated by `fitSTVAR` or STVAR.
nlags	a strictly positive integer specifying the number of lags to be tested.
which_test	should test for remaining autocorrelation or heteroskedasticity be calculated?

Details

The implemented adjusted Portmanteau test is based on Lütkepohl (2005), Section 4.4.3. When testing for remaining heteroskedasticity, the Portmanteau test is applied to squared standardized residuals that are centered to have zero mean. Note that the validity of the heteroskedasticity test requires that the residuals are not autocorrelated.

Value

A list with class "hypotest" containing the test results and arguments used to calculate the test.

```

---

print.hypotest	*Print method for the class hypotest*

Description

print.hypotest is the print method for the class hypotest objects.

Usage

```
## S3 method for class 'hypotest'
print(x, ..., digits = 4)
```

Arguments

x	object of class 'hypotest' generated by the function Wald_test, LR_test, Rao_test, or Portmenteau_test.
...	currently not in use.
digits	how many significant digits to print?

Value

Returns the input object x invisibly.

---

print.stvarsum   *Summary print method from objects of class 'stvarsum'*

Description

print.stvarsum is a print method for object 'stvarsum' generated by summary.stvar.

Usage

```
## S3 method for class 'stvarsum'
print(x, ..., digits, standard_error_print = FALSE)
```

Arguments

x	object of class 'stvarsum' generated by summary.stvar.
...	currently not used.
digits	the number of digits to be printed.
standard_error_print	
	if set to TRUE, instead of printing the estimates, prints the approximate standard errors using square roots of the diagonal of inverse of the observed information matrix.

Value

Returns the input object x invisibly.

---

profile_logliks   *Plot profile log-likelihood functions about the estimates*

Description

profile_logliks plots profile log-likelihood functions about the estimates.

Usage

```
profile_logliks(
  stvar,
  which_pars,
  scale = 0.1,
  nrows,
  ncols,
  precision = 50,
  stab_tol = 0.001,
  posdef_tol = 1e-08,
  distpar_tol = 1e-08,
  weightpar_tol = 1e-08
)
```

Arguments

stvar	an object of class 'stvar', created by, e.g., fitSTVAR or fitSSTVAR.
which_pars	the profile log-likelihood function of which parameters should be plotted? An integer vector specifying the positions of the parameters in the parameter vector. The parameter vector has the form...
scale	a numeric scalar specifying the interval plotted for each estimate: the estimate plus-minus abs(scale*estimate).
nrows	how many rows should be in the plot-matrix? The default is max(ceiling(log2(length(which_pars)) - 1), 1).
ncols	how many columns should be in the plot-matrix? The default is ceiling(length(which_pars)/nrows). Note that nrows*ncols should not be smaller than the length of which_pars.
precision	at how many points should each profile log-likelihood function be evaluated at?
stab_tol	numerical tolerance for stability of condition of the regimes: if the "bold A" matrix of any regime has eigenvalues larger that 1 - stat_tol the parameter is considered to be outside the parameter space. Note that if tolerance is too small, numerical evaluation of the log-likelihood might fail and cause error.
posdef_tol	numerical tolerance for positive definiteness of the error term covariance matrices: if the error term covariance matrix of any regime has eigenvalues smaller than this, the parameter is considered to be outside the parameter space. Note that if the tolerance is too small, numerical evaluation of the log-likelihood might fail and cause error.
distpar_tol	the parameter vector is considered to be outside the parameter space if the degrees of freedom parameters is not larger than 2 + distpar_tol (applies only if cond_dist="Student").
weightpar_tol	numerical tolerance for weight parameters being in the parameter space. Values closer to to the border of the parameter space than this are considered to be "outside" the parameter space.

Details

When the number of parameters is large, it might be better to plot a smaller number of profile log-likelihood functions at a time using the argument which_pars.

The red vertical line points the estimate.

Value

Only plots to a graphical device and doesn't return anything.

```

Rao_test   *Perform Rao's score test for a STVAR model*

Description

`Rao_test` performs Rao's score test for a STVAR model

Usage

```
Rao_test(stvar)
```

Arguments

stvar   an object of class `'stvar'` generated by `fitSTVAR` or `STVAR`, containing the model specified by the null hypothesis (i.e., **the constrained model**).

Details

Tests the constraints imposed in the model given in the argument `stvar`. This implementation uses the outer product of gradients approximation in the test statistic.

The test is based on the assumption of the standard result of asymptotic normality!

Value

A list with class "hypotest" containing the test results and arguments used to calculate the test.

redecompose_Omegas	*In the decomposition of the covariance matrices (Muirhead, 1982, Theorem A9.9), change the ordering of the covariance matrices.*

Description

redecompose_Omegas exchanges the order of the covariance matrices in the decomposition of Muirhead (1982, Theorem A9.9) and returns the new decomposition.

Usage

```
redecompose_Omegas(M, d, W, lambdas, perm = 1:M)
```

Arguments

M	the number of regimes in the model
d	the number of time series in the system
W	a length d^2 vector containing the vectorized W matrix.
lambdas	a length d*(M-1) vector of the form $\lambda_2, ..., \lambda_M$ where $\lambda_m = (\lambda_{m1}, ..., \lambda_{md})$
perm	a vector of length M giving the new order of the covariance matrices (relative to the current order)

Details

We consider the following decomposition of positive definite covariannce matrices: $\Omega_1 = WW'$, $\Omega_m = W\Lambda_m W'$, $m = 2, .., M$ where $\Lambda_m = diag(\lambda_{m1}, ..., \lambda_{md})$ contains the strictly postive eigenvalues of $\Omega_m \Omega_1^{-1}$ and the column of the invertible W are the corresponding eigenvectors. Note that this decomposition does not necessarily exists for $M > 2$.

See Muirhead (1982), Theorem A9.9 for more details on the decomposition and the source code for more details on the reparametrization.

Value

Returns a $d^2 + (M-1)d \times 1$ vector of the form `c(vec(new_W), new_lambdas)` where the lambdas parameters are in the regimewise order (first regime 2, then 3, etc) and the "new W" and "new lambdas" are constitute the new decomposition with the order of the covariance matrices given by the argument `perm`. Notice that if the first element of `perm` is one, the W matrix will be the same and the lambdas are just re-ordered.

Note that unparametrized zero elements ARE present in the returned W!

Warning

No argument checks! Does not work with dimension $d = 1$ or with only one mixture component $M = 1$.

References

• Muirhead R.J. 1982. Aspects of Multivariate Statistical Theory, *Wiley*.

Examples

```
# Create two (2x2) coviance matrices:
d <- 2 # The dimension
M <- 2 # The number of covariance matrices
Omega1 <- matrix(c(2, 0.5, 0.5, 2), nrow=d)
Omega2 <- matrix(c(1, -0.2, -0.2, 1), nrow=d)

# The decomposition with Omega1 as the first covariance matrix:
decomp1 <- diag_Omegas(Omega1, Omega2)
W <- matrix(decomp1[1:d^2], nrow=d, ncol=d) # Recover W
lambdas <- decomp1[(d^2 + 1):length(decomp1)] # Recover lambdas
tcrossprod(W) # = Omega1
W%*%tcrossprod(diag(lambdas), W) # = Omega2

reorder_B_columns	*Reorder columns of impact matrix B of a structural STVAR model that is identified by heteroskedasticity or non-Gaussianity.*

Description

`reorder_B_columns` reorder columns of impact matrix B of a structural STVAR model that is identified by heteroskedasticity or non-Gaussianity. For models identified by heteroskedasticity, also the lambda parameters are reordered accordingly. For models with ind Student or skewed t shocks, also the degrees of freedom and skewness parameters (latter for skewed t) are reordered accordingly.

Usage

```
reorder_B_columns(stvar, perm, calc_std_errors = FALSE)
```

Arguments

stvar	a class 'stvar' object defining a structural STVAR model that is identified by heteroskedasticity or non-Gaussianity, typically created with `fitSSTVAR`.
perm	an integer vector of length d specifying the new order of the columns of the impact matrix. For model identified by...

      heteroskedasticity also lambda parameters of each regime will be reordered accordingly.

      non-Gaussianity the columns of the impact matrices of all the regimes and the component specific distribution parameters (degrees of freedom and skewness parameters) are reordered accordingly.

calc_std_errors	should approximate standard errors be calculated?

Details

The order of the columns of the impact matrix can be changed without changing the implied reduced form model (as long as, for models identified by heteroskedasticity, the order of lambda parameters is also changed accordingly; and for model identified by non-Gaussianity, ordering of the columns of all the impact matrices and the component specific distribution parameters is also changed accordingly). Note that constraints imposed on the impact matrix via `B_constraints` will also be modified accordingly.

Also all signs in any column of impact matrix can be swapped (without changing the implied reduced form model, as long as signs of any skewness parameters are also swapped accordingly) with the function `swap_B_signs`. This obviously also swaps the sign constraints (if any) in the corresponding columns of the impact matrix.

Value

Returns an S3 object of class `'stvar'` defining a smooth transition VAR model. The returned list contains the following components (some of which may be `NULL` depending on the use case):

`data`	The input time series data.
`model`	A list describing the model structure.
`params`	The parameters of the model.
`std_errors`	Approximate standard errors of the parameters, if calculated.
`transition_weights`	
	The transition weights of the model.
`regime_cmeans`	Conditional means of the regimes, if data is provided.
`total_cmeans`	Total conditional means of the model, if data is provided.
`total_ccovs`	Total conditional covariances of the model, if data is provided.
`uncond_moments`	A list of unconditional moments including regime autocovariances, variances, and means.
`residuals_raw`	Raw residuals, if data is provided.
`residuals_std`	Standardized residuals, if data is provided.
`structural_shocks`	
	Recovered structural shocks, if applicable.
`loglik`	Log-likelihood of the model, if data is provided.
`IC`	The values of the information criteria (AIC, HQIC, BIC) for the model, if data is provided.
`all_estimates`	The parameter estimates from all estimation rounds, if applicable.
`all_logliks`	The log-likelihood of the estimates from all estimation rounds, if applicable.
`which_converged`	
	Indicators of which estimation rounds converged, if applicable.
`which_round`	Indicators of which round of optimization each estimate belongs to, if applicable.
`seeds`	The seeds used in the estimation in `fitSTVAR`, if applicable.
`LS_estimates`	The least squares estimates of the parameters in the form $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$ (intercepts replaced by unconditional means if mean parametrization is used), if applicable.

 simulate.stvar   *Simulate method for class 'stvar' objects*

Description

simulate.stvar is a simulate method for class 'stvar' objects.

Usage

```
## S3 method for class 'stvar'
simulate(
  object,
  nsim = 1,
  seed = NULL,
  ...,
  init_values = NULL,
  init_regime,
  ntimes = 1,
  use_stat_for_Gaus = FALSE,
  burn_in = 1000,
  exo_weights = NULL,
  drop = TRUE
)
```

Arguments

`object`	an object of class `'stvar'`.
`nsim`	number of observations to be simulated.
`seed`	set seed for the random number generator?
`...`	currently not in use.
`init_values`	a size $(p \times d)$ matrix specifying the initial values, where d is the number of time series in the system. The **last** row will be used as initial values for the first lag, the second last row for second lag etc. If not specified, initial values will be drawn from the regime specified in `init_regimes`.
`init_regime`	an integer in $1, ..., M$ specifying the regime from which the initial values should be generated from (using a simulation procedure with a burn-in period). For models with Gaussian conditional distribution, it is also possible to generate the starting values from the stationary distribution of a regime. See the details section.
`ntimes`	how many sets of simulations should be performed?
`use_stat_for_Gaus`	
	if TRUE and `cond_dist=="Gaussian"`, uses the stationary distribution of a regime to generate the initial values for the simulation. Note that if stationary distribution is used, unlike with out simulation procedure, it is not guaranteed that the regime of interest has high transition weights at the given points of time. Note that if the model allows for unstable estimates (`stvar$allow_unstab=TRUE`), simulation procedure is always used.
`burn_in`	Burn-in period for simulating initial values from a regime when `cond_dist!="Gaussian"`. See the details section.
`exo_weights`	if `weight_function="exogenous"`, provide a size $(nsim \times M)$ matrix of exogenous transition weights for the regimes: `[t, m]` for a time t and regime m weight. Ignored if `weight_function!="exogenous"`.
`drop`	if TRUE (default) then the components of the returned list are coerced to lower dimension if `ntimes==1`, i.e., `$sample` and `$transition_weights` will be matrices, and `$component` will be vector.

Details

When using `init_regime` to simulate the initial values from a given regime, we employ the following simulation procedure to obtain the initial values (unless `use_stat_for_Gaus=TRUE` and Gaussian model is considered). First, we set the initial values to the unconditional mean of the specified regime. Then, we simulate a large number observations from that regime as specified in the argument `burn_in`. Then, we simulate $p + 100$ observations more after the burn in period, and for the 100 observations calculate the transition weights for them and take the consecutive p observations that yield the highest transition weight for the given regime. For models with exogenous transition weights, takes just the last p observations after the burn-in period.

The argument `ntimes` is intended for forecasting, which is used by the predict method (see `?predict.stvar`).

Value

Returns a list containing the simulation results. If drop==TRUE and ntimes==1 (default), contains the following entries:

sample   a size (nsim×d) matrix containing the simulated time series.

transition weights

                      a size (nsim×M) matrix containing the transition weights corresponding to the simulated sample.

Otherwise, returns a list with the following entries:

sample   a size (nsim×d×ntimes) array containing the samples: the dimension [t, ,] is the time index, the dimension [, d,] indicates the marginal time series, and the dimension [, , i] indicates the i:th set of simulations.

transition_weights

                      a size (nsim×M×ntimes) array containing the transition weights corresponding to the sample: the dimension [t, ,] is the time index, the dimension [, m,] indicates the regime, and the dimension [, , i] indicates the i:th set of simulations.

## S3 method for class 'stvar'
print(x, ..., digits = 2, summary_print = FALSE, standard_error_print = FALSE)
```

Arguments

data	a matrix or class `'ts'` object with d>1 columns. Each column is taken to represent a single times series. NA values are not supported. Ignore if defining a model without data is desired.
p	a positive integer specifying the autoregressive order
M	a positive integer specifying the number of regimes
d	number of times series in the system, i.e. `ncol(data)`. This can be used to define STVAR models without data and can be ignored if data is provided.

params   a real valued vector specifying the parameter values. Should have the form $\theta = (\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \sigma, \alpha, \nu)$, where (see exceptions below):

- ϕ_m = the $(d \times 1)$ intercept (or mean) vector of the mth regime.
- $\varphi_m = (vec(A_{m,1}), ..., vec(A_{m,p}))\ (pd^2 \times 1)$.
- **if** `cond_dist="Gaussian"` **or** `"Student"`: $\sigma = (vech(\Omega_1), ..., vech(\Omega_M))$ $(Md(d+1)/2 \times 1)$.

  if `cond_dist="ind_Student"` **or** `"ind_skewed_t"`: $\sigma = (vec(B_1), ..., vec(B_M))$ $(Md^2 \times 1)$.
- α = the $(a \times 1)$ vector containing the transition weight parameters (see below).
- **if** `cond_dist = "Gaussian"`): Omit ν from the parameter vector.

  if `cond_dist="Student"`: $\nu > 2$ is the single degrees of freedom parameter.

  if `cond_dist="ind_Student"`: $\nu = (\nu_1, ..., \nu_d)\ (d \times 1)$, $\nu_i > 2$.

  if `cond_dist="ind_skewed_t"`: $\nu = (\nu_1, ..., \nu_d, \lambda_1, ..., \lambda_d)\ (2d \times 1)$, $\nu_i > 2$ and $\lambda_i \in (0, 1)$.

For models with...

`weight_function="relative_dens"`: $\alpha = (\alpha_1, ..., \alpha_{M-1})\ (M-1 \times 1)$, where $\alpha_m\ (1 \times 1)$, $m = 1, ..., M-1$ are the transition weight parameters.

`weight_function="logistic"`: $\alpha = (c, \gamma)\ (2 \times 1)$, where $c \in \mathbb{R}$ is the location parameter and $\gamma > 0$ is the scale parameter.

`weight_function="mlogit"`: $\alpha = (\gamma_1, ..., \gamma_M)\ ((M-1)k \times 1)$, where γ_m $(k \times 1)$, $m = 1, ..., M-1$ contains the multinomial logit-regression coefficients of the mth regime. Specifically, for switching variables with indices in $I \subset \{1, ..., d\}$, and with $\tilde{p} \in \{1, ..., p\}$ lags included, γ_m contains the coefficients for the vector $z_{t-1} = (1, \tilde{z}_{\min\{I\}}, ..., \tilde{z}_{\max\{I\}})$, where $\tilde{z}_i = (y_{it-1}, ..., y_{it-\tilde{p}})$, $i \in I$. So $k = 1 + |I|\tilde{p}$ where $|I|$ denotes the number of elements in I.

`weight_function="exponential"`: $\alpha = (c, \gamma)\ (2 \times 1)$, where $c \in \mathbb{R}$ is the location parameter and $\gamma > 0$ is the scale parameter.

`weight_function="threshold"`: $\alpha = (r_1, ..., r_{M-1})\ (M - 1 \times 1)$, where $r_1, ..., r_{M-1}$ are the thresholds.

`weight_function="exogenous"`: Omit α from the parameter vector.

AR_constraints: Replace $\varphi_1, ..., \varphi_M$ with ψ as described in the argument `AR_constraints`.

mean_constraints: Replace $\phi_1, ..., \phi_M$ with $(\mu_1, ..., \mu_g)$ where μ_i, $(d \times 1)$ is the mean parameter for group i and g is the number of groups.

weight_constraints: If linear constraints are imposed, replace α with ξ as described in the argument `weigh_constraints`. If weight functions parameters are imposed to be fixed values, simply drop α from the parameter vector.

`identification="heteroskedasticity"`: $\sigma = (vec(W), \lambda_2, ..., \lambda_M)$, where $W\ (d \times d)$ and $\lambda_m\ (d \times 1)$, $m = 2, ..., M$, satisfy $\Omega_1 = WW'$ and $\Omega_m = W\Lambda_m W'$, $\Lambda_m = diag(\lambda_{m1}, ..., \lambda_{md})$, $\lambda_{mi} > 0$, $m = 2, ..., M$, $i = 1, ..., d$.

B_constraints: For models identified by heteroskedasticity, replace $vec(W)$ with $v\tilde{e}c(W)$ that stacks the columns of the matrix W in to vector so that the elements that are constrained to zero are not included. For models identified by non-Gaussianity, replace $vec(B_1), ..., vec(B_M)$ with similarly with vectorized versions B_m so that the elements that are constrained to zero are not included.

Above, ϕ_m is the intercept parameter, $A_{m,i}$ denotes the ith coefficient matrix of the mth regime, Ω_m denotes the positive definite error term covariance matrix of the mth regime, and B_m is the invertible $(d \times d)$ impact matrix of the mth regime. ν_m is the degrees of freedom parameter of the mth regime. If `parametrization=="mean"`, just replace each ϕ_m with regimewise mean μ_m. $vec()$ is vectorization operator that stacks columns of a given matrix into a vector. $vech()$ stacks columns of a given matrix from the principal diagonal downwards (including elements on the diagonal) into a vector. $Bvec()$ is a vectorization operator that stacks the columns of a given impact matrix B_m into a vector so that the elements that are constrained to zero by the argument `B_constraints` are excluded.

weight_function

What type of transition weights $\alpha_{m,t}$ should be used?

`"relative_dens"`: $\alpha_{m,t} = \frac{\alpha_m f_{m,dp}(y_{t-1},...,y_{t-p+1})}{\sum_{n=1}^{M} \alpha_n f_{n,dp}(y_{t-1},...,y_{t-p+1})}$, where $\alpha_m \in (0,1)$ are weight parameters that satisfy $\sum_{m=1}^{M} \alpha_m = 1$ and $f_{m,dp}(\cdot)$ is the dp-dimensional stationary density of the mth regime corresponding to p consecutive observations. Available for Gaussian conditional distribution only.

`"logistic"`: $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = [1 + \exp\{-\gamma(y_{it-j} - c)\}]^{-1}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

`"mlogit"`: $\alpha_{m,t} = \frac{\exp\{\gamma_m' z_{t-1}\}}{\sum_{n=1}^{M} \exp\{\gamma_n' z_{t-1}\}}$, where γ_m are coefficient vectors, $\gamma_M = 0$, and z_{t-1} $(k \times 1)$ is the vector containing a constant and the (lagged) switching variables.

`"exponential"`: $M = 2$, $\alpha_{1,t} = 1 - \alpha_{2,t}$, and $\alpha_{2,t} = 1 - \exp\{-\gamma(y_{it-j} - c)\}$, where y_{it-j} is the lag j observation of the ith variable, c is a location parameter, and $\gamma > 0$ is a scale parameter.

`"threshold"`: $\alpha_{m,t} = 1$ if $r_{m-1} < y_{it-j} \leq r_m$ and 0 otherwise, where $-\infty \equiv r_0 < r_1 < \cdots < r_{M-1} < r_M \equiv \infty$ are thresholds y_{it-j} is the lag j observation of the ith variable.

`"exogenous"`: Exogenous nonrandom transition weights, specify the weight series in `weightfun_pars`.

See the vignette for more details about the weight functions.

weightfun_pars **If** `weight_function == "relative_dens"`: Not used.

If `weight_function %in% c("logistic", "exponential", "threshold")`: a numeric vector with the switching variable $i \in \{1, ..., d\}$ in the first and the lag $j \in \{1, ..., p\}$ in the second element.

If `weight_function == "mlogit"`: a list of two elements:

The first element `$vars`: a numeric vector containing the variables that should used as switching variables in the weight function in an increasing order, i.e., a vector with unique elements in $\{1, ..., d\}$.

The second element `$lags:` an integer in $\{1, ..., p\}$ specifying the number of lags to be used in the weight function.

If `weight_function == "exogenous"`: a size `(nrow(data) - p x M)` matrix containing the exogenous transition weights as `[t, m]` for time t and regime m. Each row needs to sum to one and only weakly positive values are allowed.

cond_dist   specifies the conditional distribution of the model as `"Gaussian"`, `"Student"`, `"ind_Student"`, or `"ind_skewed_t"`, where `"ind_Student"` the Student's t distribution with independent components, and `"ind_skewed_t"` is the skewed t distribution with independent components (see Hansen, 1994).

parametrization

"intercept" or "mean" determining whether the model is parametrized with intercept parameters ϕ_m or regime means μ_m, m=1,...,M.

identification is it reduced form model or an identified structural model; if the latter, how is it identified (see the vignette or the references for details)?

"reduced_form": Reduced form model.

"recursive": The usual lower-triangular recursive identification of the shocks via their impact responses.

"heteroskedasticity": Identification by conditional heteroskedasticity, which imposes constant relative impact responses for each shock.

"non-Gaussianity": Identification by non-Gaussianity; requires mutually independent non-Gaussian shocks, thus, currently available only with the conditional distribution "ind_Student".

AR_constraints a size $(Mpd^2 \times q)$ constraint matrix C specifying linear constraints to the autoregressive parameters. The constraints are of the form $(\varphi_1, ..., \varphi_M) = C\psi$, where $\varphi_m = (vec(A_{m,1}), ..., vec(A_{m,p}))$ $(pd^2 \times 1)$, $m = 1, ..., M$, contains the coefficient matrices and ψ $(q \times 1)$ contains the related parameters. For example, to restrict the AR-parameters to be the identical across the regimes, set $C = [I : ... : I]'$ $(Mpd^2 \times pd^2)$ where `I = diag(p*d^2)`.

mean_constraints

Restrict the mean parameters of some regimes to be identical? Provide a list of numeric vectors such that each numeric vector contains the regimes that should share the common mean parameters. For instance, if M=3, the argument `list(1, 2:3)` restricts the mean parameters of the second and third regime to be identical but the first regime has freely estimated (unconditional) mean. Ignore or set to NULL if mean parameters should not be restricted to be the same among any regimes. This constraint is available only for mean parametrized models; that is, when `parametrization="mean"`.

weight_constraints

a list of two elements, R in the first element and r in the second element, specifying linear constraints on the transition weight parameters α. The constraints are of the form $\alpha = R\xi + r$, where R is a known $(a \times l)$ constraint matrix of full column rank (a is the dimension of α), r is a known $(a \times 1)$ constant, and ξ is an unknown $(l \times 1)$ parameter. **Alternatively**, set $R = 0$ to constrain the weight parameters to the constant r (in this case, α is dropped from the constrained parameter vector).

B_constraints   a $(d \times d)$ matrix with its entries imposing constraints on the impact matrix B_t:
                 NA indicating that the element is unconstrained, a positive value indicating strict
                 positive sign constraint, a negative value indicating strict negative sign con-
                 straint, and zero indicating that the element is constrained to zero. Currently
                 only available for models with identification="heteroskedasticity" or
                 "non-Gaussianity" due to the (in)availability of appropriate parametrizations
                 that allow such constraints to be imposed.

penalized   Perform penalized LS estimation that minimizes penalized RSS in which esti-
                 mates close to breaking or not satisfying the usual stability condition are penal-
                 ized? If TRUE, the tuning parameter is set by the argument penalty_params[2],
                 and the penalization starts when the eigenvalues of the companion form AR ma-
                 trix are larger than 1 - penalty_params[1].

penalty_params   a numeric vector with two positive elements specifying the penalization param-
                 eters: the first element determined how far from the boundary of the stability
                 region the penalization starts (a number between zero and one, smaller number
                 starts penalization closer to the boundary) and the second element is a tuning
                 parameter for the penalization (a positive real number, a higher value penalizes
                 non-stability more).

allow_unstab   If TRUE, estimates not satisfying the stability condition are allowed. Always
                 FALSE if weight_function="relative_dens".

calc_std_errors
                 should approximate standard errors be calculated?

object   object of class 'stvar'.

...   currently not used.

digits   number of digits to be printed.

standard_error_print
                 if set to TRUE, instead of printing the estimates, prints the approximate standard
                 errors using square roots of the diagonal of inverse of the observed information
                 matrix.

x   an object of class 'stvar'.

plot_type   should the series be plotted with the estimated transition weights or conditional
                 means?

summary_print   if set to TRUE then the print will include log-likelihood and information criteria
                 values.

Details

If data is provided, then also residuals are computed and included in the returned object.

The plot displays the time series together with estimated transition weights.

Value

Returns an S3 object of class 'stvar' defining a smooth transition VAR model. The returned list
contains the following components (some of which may be NULL depending on the use case):

data   The input time series data.

`model`	A list describing the model structure.
`params`	The parameters of the model.
`std_errors`	Approximate standard errors of the parameters, if calculated.
`transition_weights`	
	The transition weights of the model.
`regime_cmeans`	Conditional means of the regimes, if data is provided.
`total_cmeans`	Total conditional means of the model, if data is provided.
`total_ccovs`	Total conditional covariances of the model, if data is provided.
`uncond_moments`	A list of unconditional moments including regime autocovariances, variances, and means.
`residuals_raw`	Raw residuals, if data is provided.
`residuals_std`	Standardized residuals, if data is provided.
`structural_shocks`	
	Recovered structural shocks, if applicable.
`loglik`	Log-likelihood of the model, if data is provided.
`IC`	The values of the information criteria (AIC, HQIC, BIC) for the model, if data is provided.
`all_estimates`	The parameter estimates from all estimation rounds, if applicable.
`all_logliks`	The log-likelihood of the estimates from all estimation rounds, if applicable.
`which_converged`	
	Indicators of which estimation rounds converged, if applicable.
`which_round`	Indicators of which round of optimization each estimate belongs to, if applicable.
`seeds`	The seeds used in the estimation in `fitSTVAR`, if applicable.
`LS_estimates`	The least squares estimates of the parameters in the form $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$ (intercepts replaced by unconditional means if mean parametrization is used), if applicable.

Functions

- `logLik(stvar)`: Log-likelihood method
- `residuals(stvar)`: residuals method to extract Pearson residuals
- `summary(stvar)`: summary method
- `plot(stvar)`: plot method for class 'stvar'
- `print(stvar)`: print method

About S3 methods

If data is not provided, only the `print` and `simulate` methods are available. If data is provided, then in addition to the ones listed above, `predict` method is also available. See `?simulate.stvar` and `?predict.stvar` for details about the usage.

stvar_to_sstvars110	*Update STVAR model estimated with a version of the package <1.1.0 to be compatible with the versions >=1.1.0.*

Description

update_stvar_to_sstvar110 updates a STVAR model estimated with a version of the package <1.1.0 to be compatible with the versions >=1.1.0 by adding the elements $penalized, $penalty_params, and $allow_unstab to the model object.

Usage

```
stvar_to_sstvars110(stvar)
```

Arguments

stvar   object of class "stvar"

Details

The function is useful when a STVAR model estimated with a version of the package <1.1.0. Does not do anything if the elements $penalized, $penalty_params, and $allow_unstab are already containing in the model object.

Value

Returns an object of class 'stvar' with the elements $penalized, $penalty_params, and $allow_unstab added to it if they were missing.

Examples

```
# Linear Gaussian VAR(p=1) model:
theta_112 <- c(0.649526, 0.066507, 0.288526, 0.021767, -0.144024, 0.897103,
  0.601786, -0.002945, 0.067224)
mod112 <- STVAR(data=gdpdef, p=1, M=1, params=theta_112)

# Update to include the new elements (does not do anything if they are already
# included):
mod112 <- stvar_to_sstvars110(mod112)
```

---

swap_B_signs	*Swap all signs in pointed columns of the impact matrix of a structural STVAR model that is identified by heteroskedasticity or non-Gaussianity*

Description

swap_B_signs swaps all signs in pointed columns of the impact matrix of a structural STVAR model that is identified by heteroskedasticity or non-Gaussianity. For ind skewed t models, also the signs of the skewness parameters are swapped accordingly.

Usage

```
swap_B_signs(stvar, which_to_swap, calc_std_errors = FALSE)
```

Arguments

stvar	a class 'stvar' object defining a structural STVAR model that is identified by heteroskedasticity or non-Gaussianity, typically created with fitSSTVAR.
which_to_swap	a numeric vector of length at most d and elemnts in $1,..,d$ specifying the columns of the impact matrix whose sign should be swapped.
calc_std_errors	should approximate standard errors be calculated?

Details

All signs in any column of the impact matrix can be swapped without changing the implied reduced form model, but for ind skewed t models, also the signs of the corresponding skewness parameter values need to be swapped. For model identified by non-Gaussianity, the signs of the columns of the impact matrices of all the regimes are swapped accordingly. Note that the sign constraints imposed on the impact matrix via B_constraints are also swapped in the corresponding columns accordingly.

Also the order of the columns of the impact matrix can be changed (without changing the implied reduced form model) as long as the ordering of other related parameters is also changed accordingly. This can be done with the function reorder_B_columns.

Value

Returns an S3 object of class 'stvar' defining a smooth transition VAR model. The returned list contains the following components (some of which may be NULL depending on the use case):

data	The input time series data.
model	A list describing the model structure.
params	The parameters of the model.
std_errors	Approximate standard errors of the parameters, if calculated.
transition_weights	
	The transition weights of the model.
regime_cmeans	Conditional means of the regimes, if data is provided.
total_cmeans	Total conditional means of the model, if data is provided.
total_ccovs	Total conditional covariances of the model, if data is provided.
uncond_moments	A list of unconditional moments including regime autocovariances, variances, and means.
residuals_raw	Raw residuals, if data is provided.
residuals_std	Standardized residuals, if data is provided.
structural_shocks	
	Recovered structural shocks, if applicable.
loglik	Log-likelihood of the model, if data is provided.
IC	The values of the information criteria (AIC, HQIC, BIC) for the model, if data is provided.
all_estimates	The parameter estimates from all estimation rounds, if applicable.
all_logliks	The log-likelihood of the estimates from all estimation rounds, if applicable.
which_converged	
	Indicators of which estimation rounds converged, if applicable.
which_round	Indicators of which round of optimization each estimate belongs to, if applicable.
seeds	The seeds used in the estimation in fitSTVAR, if applicable.
LS_estimates	The least squares estimates of the parameters in the form $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$ (intercepts replaced by unconditional means if mean parametrization is used), if applicable.

swap_parametrization   *Swap the parametrization of a STVAR model*

Description

swap_parametrization swaps the parametrization of a STVAR model to "mean" if the current
parametrization is "intercept", and vice versa.

Usage

```
swap_parametrization(stvar, calc_std_errors = FALSE)
```

Arguments

stvar   object of class "stvar"

calc_std_errors

         should approximate standard errors be calculated?

Details

swap_parametrization is a convenient tool if you have estimated the model in "intercept" parametrization but wish to work with "mean" parametrization in the future, or vice versa.

Value

Returns an S3 object of class 'stvar' defining a smooth transition VAR model. The returned list contains the following components (some of which may be NULL depending on the use case):

data	The input time series data.
model	A list describing the model structure.
params	The parameters of the model.
std_errors	Approximate standard errors of the parameters, if calculated.
transition_weights	
	The transition weights of the model.
regime_cmeans	Conditional means of the regimes, if data is provided.
total_cmeans	Total conditional means of the model, if data is provided.
total_ccovs	Total conditional covariances of the model, if data is provided.
uncond_moments	A list of unconditional moments including regime autocovariances, variances, and means.
residuals_raw	Raw residuals, if data is provided.
residuals_std	Standardized residuals, if data is provided.
structural_shocks	
	Recovered structural shocks, if applicable.
loglik	Log-likelihood of the model, if data is provided.
IC	The values of the information criteria (AIC, HQIC, BIC) for the model, if data is provided.
all_estimates	The parameter estimates from all estimation rounds, if applicable.
all_logliks	The log-likelihood of the estimates from all estimation rounds, if applicable.
which_converged	
	Indicators of which estimation rounds converged, if applicable.
which_round	Indicators of which round of optimization each estimate belongs to, if applicable.
seeds	The seeds used in the estimation in fitSTVAR, if applicable.
LS_estimates	The least squares estimates of the parameters in the form $(\phi_1, ..., \phi_M, \varphi_1, ..., \varphi_M, \alpha$ (intercepts replaced by unconditional means if mean parametrization is used), if applicable.

  calc_std_errors=TRUE)
print(mod112, standard_error_print=TRUE) # Standard errors are printed for the intercepts

# To obtain standard errors for the unconditional means instead of the intercepts,
# swap to mean parametrization:
mod112mu <- swap_parametrization(mod112, calc_std_errors=TRUE)
print(mod112mu, standard_error_print=TRUE) # Standard errors are printed for the means
```

---

uncond_moments	*Calculate the unconditional means, variances, the first p autocovariances, and the first p autocorrelations of the regimes of the model.*

Description

`uncond_moments` calculates the unconditional means, variances, the first p autocovariances, and the first p autocorrelations of the regimes of the model.

Usage

```
uncond_moments(stvar)
```

Arguments

stvar	object of class "stvar"

Value

Returns a list with three components:

`$regime_means` a $M \times d$ matrix vector containing the unconditional mean of the regime m in the mth column.

`$regime_vars` a $M \times d$ matrix vector containing the unconditional marginal variances of the regime m in the mth column.

`$regime_autocovs` an $(dxdxp + 1, M)$ array containing the lag 0,1,...,p autocovariances of the process. The subset `[, , j, m]` contains the lag j-1 autocovariance matrix (lag zero for the variance) for the regime m.

`$regime_autocors` the autocovariance matrices scaled to autocorrelation matrices.

usacpu   *U.S. climate policy uncertainty, economic policy uncertainty, industrial production, consumer price index,*

Description

A monthly U.S. data covering the period from 1987:4 to 2024:12 (453 observations) and consisting five variables. First, the climate policy uncertainty index (CPUI) (Gavridiilis, 2021), which is a news based measure of climate policy uncertainty. Second, the economic policy uncertainty index (EPUI), which is a news based measure of economic policy uncertainty, including also components quantifying the present value of future scheduled tax code expirations and disagreement among professional forecasters over future goverment purchases and consumer prices. Third, the log-difference of real indsitrial production index (IPI). Fourth, the log-difference of the consumer price index (CPI). Fifth, an interest rate variable (RATE), which is the effective federal funds rate that is replaced by the the Wu and Xia (2016) shadow rate during zero-lower-bound periods. The Wu and Xia (2016) shadow rate is not bounded by the zero lower bound and also quantifies unconventional monetary policy measures, while it closely follows the federal funds rate when the zero lower bound does not bind. This is the dataset used in Virolainen (2025)

Usage

usacpu

Format

A numeric matrix of class `'ts'` with 443 rows and 4 columns with one time series in each column:

First column (CPUI): The climate policy uncertainty index, https://www.policyuncertainty.com/climate_uncertainty.html.

Second column (EPUI): The economic policy uncertainty index, https://www.policyuncertainty.com/us_monthly.html.

Third column (IPI): The log-difference of real indsitrial production index, https://fred.stlouisfed.org/series/INDPRO.

Fourth column (CPI): The log-difference of the consumer price index, https://fred.stlouisfed.org/series/CPIAUCSL.

Fifth column (RATE): The Federal funds rate from 1954Q3 to 2008Q2 and after that the Wu and Xia (2016) shadow rate, https://fred.stlouisfed.org/series/FEDFUNDS, https://www.atlantafed.org/cqer/research/wu-xia-shadow-federal-funds-rate.

usamone | *U.S. real GDP, GDP implicit price deflator, and interest rate data*

Description

A quarterly U.S. data covering the period from 1954Q3 to 2021Q4 (270 observations) and consisting three variables: cyclical component of the log of real GDP, the log-difference of GDP implicit price deflator, and an interest rate variable. The interest rate variable is the effective federal funds rate from 1954Q3 to 2008Q2 and after that the Wu and Xia (2016) shadow rate, which is not constrained by the zero lower bound and also quantifies unconventional monetary policy measures. The log-differences of the GDP deflator and producer price index are multiplied by hundred.

The cyclical component of the log of real GDP was obtained by applying a one-sided Hodrick-Prescott (HP) filter with the standard smoothing parameter lambda=1600. The one-sided filter was obtained from the two-sided HP filter by applying the filter up to horizon t, taking the last observation, and repeating this procedure for the full sample t=1,...,T. In order to allow the series to start from any phase of the cycle, we applied the one-sided filter to the full available sample from 1947Q1 to 2021Q1 before extracting our sample period from it. We computed the two-sided HP filters with the R package lpirfs (Adämmer, 2021)

Usage

Wald_test   *Perform Wald test for a STVAR model*

Description

`Wald_test` performs a Wald test for a STVAR model

Usage

```
Wald_test(stvar, A, c)
```

Arguments

stvar	an object of class `'stvar'` generated by `fitSTVAR` or `STVAR`, containing the model specified by the alternative hypothesis (i.e., **the unconstrained model**).
A	a size $(k \times$ n_params$)$ matrix with full row rank specifying a part of the null hypothesis where n_params is the number of parameters in the (unconstrained) model. See details for more information.
c	a length k vector specifying a part of the null hypothesis. See details for more information.

Details

Denoting the true parameter value by θ_0, we test the null hypothesis $A\theta_0 = c$. Under the null, the test statistic is asymptotically χ^2-distributed with k (=nrow(A)) degrees of freedom. The parameter θ_0 is assumed to have the same form as in the model supplied in the argument stvar and it is presented in the documentation of the argument params in the function STVAR (see ?STVAR).

The test is based on the assumption of the standard result of asymptotic normality! Also note that this function does **not** check whether the model assumptions hold under the null.

Value

A list with class "hypotest" containing the test results and arguments used to calculate the test.
